[M. Nélaton met with a case of compound dislocation of the internal cuneiform bone, caused by the wheel of a carriage passing over the foot. The wound corresponded to the cuneo-scaphoid articulation, and the posterior and inferior angle of the cuneiform bone protruded through it. The bone was displaced in such a manner as to rest transversely upon the middle cuneiform. The reduction being found impracticable, the dislocated bone was removed, and the patient did well. (See *Elém de Pathol. Chir.* t. ii. p. 488.)

A case of dislocation of all *three cuneiform bones* was treated by Mr. Luke in the London Hospital. The three cuneiform bones appeared to be partially dislocated upwards. The internal cuneiform bone was chiefly displaced from the navicular bone, and projected upwards and inwards. By extension from the toes and by pressure upon the displaced bones, they were returned after some time, with an evident sensation. The inflammation which followed was subdued by leeches and cold lotion. The strength in the foot returned slowly, and the patient was not able to bear on it or to walk till six weeks after the accident. (*Lond. Med. Gaz.* 1831, vol. vii. p. 704.)

A case of compound dislocation of the *middle and external cuneiform bones* has been recorded by Mr. Aston Key. The skin and the tendons on the dorsum of the foot had suffered serious laceration, and the fourth and fifth metatarsal bones were also fractured. The middle and external cuneiform bones were partially dislocated, forming two distinct square swellings on the dorsum of the foot, but inferiorly remaining wedged in their places. By drawing the anterior part of the foot forwards, in a line at right angles with the leg, from which counter-extension was kept up, and at the same time pressing with the thumbs upon the dislocated bones, Mr. Key succeeded in reducing them, and they slipped into their places with a snap. The integuments on the dorsum of the foot sloughed, and

a succession of abscesses formed, but the patient ultimately recovered with a scarcely perceptible lameness. (See *Guy's Hospital Reports*, vol. i. 1836, p. 244.)]

[DISLOCATIONS AT THE TARSO-METATARSAL ARTICULATIONS.]

[Dislocations at the tarso-metatarsal articulations have been occasionally seen. The dislocation may implicate the whole range of metatarsal bones, or any lesser number of them.

Dislocation of a single metatarsal bone.—A case of dislocation of the *first* metatarsal bone upwards was met with by Mr. Liston, who succeeded in reducing it. A dislocation of the *fourth* metatarsal bone upwards and backwards on to the cuboid was observed by M. Malgaigne, and was caused by a fall on to the anterior part of the sole of the foot; he endeavoured to reduce it by making extension upon the toe, and by pressing upon the end of the metatarsal bone downwards and forwards. These means failing, he inserted a pointed instrument into the posterior articular surface, and with it pressed the head of the bone in the proper direction. After several attempts it slipped into its place.

Dislocation of two metatarsal bones.—A case of dislocation of the fourth and fifth metatarsal bones upwards and backwards on the cuboid was admitted into St. Thomas's Hospital under Mr. Green. The dislocation was caused by the falling of a heavy cask upon the inside of the foot. The bones were reduced by continued extension with much difficulty, and as they recovered their place a distinct crackling was heard. (*South's translation of Chelius*, vol. i. p. 814.) Another instance of dislocation of the same two bones upwards and slightly inwards has been related by Monteggia. (See *Malgaigne, Traité des Fract.* t. ii. p. 1078.)

Dislocation of three metatarsal bones.—A *partial* dislocation *upwards* of the three first metatarsal bones was observed by M. Laugier, and was readily reduced. Mr. Tufnell records a case of dislocation of the same three bones *downwards*. It happened in a soldier whose horse fell with him, and crushed his foot against the ground. The foot was found to be much shortened, curved inwards, and bent, the tarsus presented a hard bony projection overhanging the metatarsus, whilst deep under the plantar surface a second bony mass could be felt lying obliquely across the sole of the foot. All attempts at reduction proved unavailing; the patient six months afterwards was able to walk freely with a stick, bearing his weight upon the outer border of the sole of the foot, as in a case of talipes varus. (See *Tufnell, Dublin Quart. Journ. of Med. Science*, Feb. 1854, p. 65.)

M. Malgaigne met with two instances of dislocation upwards of the second, third, and fourth metatarsal bones. In one of these the displacement was incomplete; the accident had occurred many years previously, and had remained unreduced; but at the time the patient came under M. Malgaigne's observation he was able to walk perfectly well. In the second case the dislocation was complete, and the metatarsal bones rested on the dorsal surface of the tarsus. Reduction was found impracticable. This patient died, and the state of the parts was verified by dissection. (See *Malgaigne, Traité des Fract.* t. ii. p. 1078.)

Dislocation of four metatarsal bones.—M. Mal-

gaigne met with a dislocation of the four first metatarsal bones, caused by the fall of a horse upon the patient's foot. The three first metatarsal bones were dislocated *downwards*, but the fourth was partially displaced *upwards*. The internal border of the foot was shortened nearly half an inch, showing that there was overlapping of the bones to a like extent. The vertical diameter of the foot was increased by about four-fifths of an inch. In this case reduction was impossible, so far as regarded the three first metatarsal bones, but the fourth was pressed downwards into its place. In course of time, however, this patient completely recovered the use of his foot.

Dislocations of all the metatarsal bones.—The entire metatarsus has been seen dislocated from the tarsus in four different directions—upwards, downwards, outwards, and inwards. The upward dislocation is by far the most frequent, for out of twelve examples, to which M. Malgaigne refers, there were eight dislocations upwards, one downwards, two outwards, and one inwards. Only one of the twelve was a compound dislocation.

Dislocation upwards.—In the dislocation upwards it sometimes happens that the first metatarsal bone is not dislocated from the internal cuneiform, but the internal cuneiform is separated from the scaphoid, and is dislocated upwards with the metatarsus. Mr. R. W. Smith first called attention to this form of dislocation, and has given a detailed account of the dissection of two cases of this kind; according to M. Malgaigne, four out of the eight cases of dislocation upwards presented this peculiarity. Mr. Smith thinks the internal cuneiform bone is more likely to remain connected with the first metatarsal bone than with the scaphoid, in consequence of the strong connection maintained between it and the first metatarsal by means of the tendons of the peroneus longus and tibialis anticus; each of which tendons having an attachment to each of the bones in question, must constitute a powerful means of preventing their separation from one another.

In these dislocations the prominence of the tarsus on the dorsum of the foot is easily made out, and the projection of the tarsus downwards is usually also to be distinguished. The anterior part of the foot is shortened more or less, according to the extent to which the bones overlap each other. The form of the prominence on the dorsum of the foot will enable the surgeon to distinguish whether the case is a pure dislocation of the metatarsus, or whether the internal cuneiform is included in the displacement. The two cases dissected by Mr. Smith were instances of old unreduced dislocation; in both the plantar region, instead of presenting its natural concavity, was convex, both in the antero-posterior and transverse diameters; the sole of the foot was directed inwards, and its outer border, in standing and walking, was presented to the ground. A like tendency to inversion of the foot has been observed in other cases. The only case in which the dislocation was compound was observed by M. Mazet. Here the limb was amputated, and its condition was afterwards carefully examined. The three middle metatarsal bones were dislocated upwards on to the tarsus, but the fifth was thrown outwards from the cuboid, and rotated so that its internal surface looked upwards, and the first metatarsal was dislocated inwards from the internal cuneiform. A drawing of this

preparation is given by M. Malgaigne. (See pl. xxx. fig. 6.)

Reduction.—In three cases under MM. Dupuytren, Bouchard, and Meynier, the dislocation was easily reduced, by pulling upon the metatarsal bones, and by making pressure also upon their dislocated extremities. All three patients did well; but in Dupuytren's case, at the end of seven or eight weeks there was still some inconvenience in walking. In a fourth case, under M. Delort, reduction was also obtained, but the patient died from internal injuries. In one case, under Dupuytren, all attempts at reduction were fruitless, but the patient was not seen by him till three weeks after the accident. In the two cases recorded by Mr. R. W. Smith it was not known whether any attempt had been made at the time to reduce the dislocation. In the remaining case, that of M. Mazet, the limb was amputated. (See *Malgaigne, Traité des Fract. t. ii. p. 1077*, and *R. W. Smith, On Fractures and Dislocations, p. 224. Dublin, 1847.*)

Dislocation downwards.—The only recorded case of dislocation of the metatarsus downwards is related by Mr. Smyly of Dublin. It happened in a young man, in consequence of the upsetting of a cart which he was driving. He fell so that his right foot got between the shaft and the bank of a ditch, the shaft crushing the heel against the toes, which were fixed by the bank. The foot was at first so swollen that the nature of the accident could not be ascertained, but when the ecchymosis was dispersed, the injury became manifest from the projection of the tarsus, the hollow immediately in front of it, with the corresponding projection in the sole, and the shortening of the foot. On the sixth day the dislocation was reduced by means of pulleys. A piece of wood in the form of a sandal, made to fit the sole of the foot, having a heel-piece of leather, with a strap to cross the instep, retained the bones in their places. Three weeks after the accident the man was sufficiently recovered to use his foot. (See *Dublin Quart. Journ. of Med. Science, May 1854, p. 317.*)

Dislocation outwards.—Two examples of dislocation of the metatarsus outwards have been observed. In one the second metatarsal bone was fractured; in the other, the four outer metatarsal bones were dislocated *upwards* as well as outwards. The manner in which the second metatarsal bone is wedged between the three cuneiform bones would, probably, always prevent this bone being displaced *directly* outwards with the rest without fracture. In the first case, seen by M. Laugier, the accident was caused by the patient falling from a height in such a manner that the weight of the body came upon the anterior part of the external border of the foot. The toes must, therefore, have been carried inwards, and the base of the metatarsus twisted outwards. The internal cuneiform bone was prominent at the internal border of the foot, and a portion of its anterior articular surface could be felt; the fifth metatarsal bone was in like manner unduly prominent externally. A fracture of the second metatarsal bone, towards its middle part, could be distinguished. The reduction was easily obtained by making pressure upon the tarsus outwards and the metatarsus inwards. The patient recovered favourably. In the other case, which is recorded by M. Lacombe, and which occurred in his own person, the accident was caused in a different manner, for

the force operated against the anterior part of the *inner border* of the foot, so as to press it outwards. The fore part of the foot was thrown outwards and formed an obtuse angle with the cuboid and os calcis. The fifth metatarsal bone was prominent on the outer side and the internal cuneiform internally, but the four outer metatarsal bones were also dislocated upwards, and overlapped the tarsus in this direction more than half an inch, causing an evident shortening of the foot. The reduction was attempted by traction with the hands only, it being found impossible to apply a bandage round the foot for the purpose of making extension, in consequence of the tendency of the metatarsal bones to overlap each other. Complete reduction was impossible; but the position of the foot was much improved. Ultimately M. Lacombe, by means of an apparatus specially modelled to fit the foot, was able to resume his avocations.

Dislocation inwards.—A case of dislocation of the metatarsus *inwards* is recorded by Mr. Kirk of Glasgow. Here the metatarsus was driven inwards, and formed a projection to the extent of an inch on the inside of the foot, and left a corresponding depression on the outside. The reduction was easily accomplished by grasping the metatarsus in one hand and the tarsus in the other, and pulling or pressing in the direction calculated to bring the articular surfaces into apposition. (See *Lond. Med. Gaz.* 1844, vol. xxxiv. p. 440.)]

[DISLOCATIONS AT THE METATARSO-PHALAN-
GEAL ARTICULATIONS.]

[*Dislocations of the great toe.*—M. Malgaigne refers to nineteen recorded cases of dislocation of the first phalanx of the great toe from its metatarsal bone. Of these nine were simple and ten were compound dislocations. The mode in which the accident was produced is mentioned in seventeen cases: in ten of these the cause was the fall of a horse, the foot of the patient being usually engaged beneath the fallen animal; four times it was produced by the wheel of a carriage; twice by a fall on the toe from an elevated position. It appears probable, also, that at the moment of the accident, the toe is usually forcibly bent backwards upon the metatarsal bone.

In the simple dislocation the toe is, in the great majority of cases, displaced directly *upwards*; occasionally obliquely upwards and inwards. The head of the phalanx is prominent on the dorsal aspect of the foot, and the head of the metatarsal bone forms a projection towards the sole. The dislocation may be complete or incomplete: if complete, the deformity is very considerable, the bones may overlap each other, and shortening of the toe will then be observed; if incomplete, the deformity is of course less, and shortening is impossible. The point of the toe is inclined a little outwards, and usually preserves its natural level; sometimes, however, it is slightly flexed; and, on the other hand, it has sometimes been seen raised to a right angle upon the metatarsal bone.

Reduction.—As in the corresponding joint of the thumb, the reduction is often attended with great difficulty, and has sometimes been found impossible. The difficulty, probably, arises from the same causes as in the thumb, and, as they have been fully explained in speaking of the dislocation of that part, it is not necessary here to repeat them. All the manoeuvres recommended for the thumb

are also applicable to the great toe. If the sesamoid bones and the anterior ligament are the chief obstacles, as Dr. A. Laurie believed, and which opinion is corroborated by the authority of Sir A. Cooper, the plan which appears most likely to succeed is that of bending the toe backwards on the metatarsal bone, and pushing the dislocated end of the phalanx forwards; then, when its plantar edge has been made to overlap the metatarsal bone, bringing it gradually downwards towards the straight line. (See DISLOCATIONS OF THUMB.) In obstinate cases, section of the extensor tendons has been tried, and section of the extensor tendons and internal lateral ligament also; but equally without effect.

Compound dislocation of the great toe.—When the dislocation is compound, the wound is almost invariably on the inner side of the foot. The head of the metatarsal bone projects through it, and the phalanx is dislocated upwards and outwards. The great toe is inclined outwards, across the others; sometimes forming nearly a right angle with them. In some instances, however, the displacement has appeared to belong rather to the metatarsal bone than to the phalanx, for the toe has preserved its normal position and direction, but the head of the metatarsal bone has been inclined downwards. In one example, the displacement of the head of this bone downwards has been combined with displacement of its tarsal extremity upwards, so that in reality it had been subjected to a double dislocation.

Treatment.—In six of the ten cases to which M. Malgaigne refers the dislocation was reduced, but not always without difficulty. In five of these suppuration took place on the outer side of the metatarsal bone: one of the patients died; three recovered with ankylosis, after exfoliation of the articular cartilages; the fifth also recovered, but whether with ankylosis or not is not stated. The sixth case recovered, and was the only one in which the movements of the joint were preserved: here the wound in the skin was enlarged, and an incision was also made along the outer side of the metatarsal bone, which gave exit to some coagulated blood.

In four examples reduction was impracticable. In two of these the head of the metatarsal bone was excised: one of the patients, a cavalry soldier, was able to resume his duty; the other patient died. In the two others the entire metatarsal bone was excised, but with what object so severe a measure was resorted to it is not easy to understand: in both these cases the usefulness of the foot was very materially impaired.

Sir A. Cooper met with a case of dislocation of the *four outer toes from their metatarsal bones*. Upon examination of the bottom of the foot, a considerable projection was found at the roots of all the smaller toes, the extremity of each of the metatarsal bones being placed under the first phalanx of its corresponding toe. Several months had elapsed from the time of the accident, and at first, from the swelling of the foot, it had not been detected. No extension would have been likely to answer any purpose, and the only mode of relief was to wear a piece of hollow cork at the bottom of the inner part of the shoe, to prevent the pressure of the metatarsal bones upon the nerves and blood vessels. (*On Dislocations*, B. Cooper's ed. p. 339.)

An instance of dislocation of *all the toes from the metatarsal bones* has been recorded by M. Josse

of Amiens. It happened in a dragoon, in consequence of his horse falling with him and squeezing his foot against the ground. The toes were dislocated outwards, and the head of the first metatarsal bone escaped through a transverse wound on the inner side of the articulation. Reduction was attempted, but the protruding extremity of the metatarsal bone opposed an insurmountable resistance. It was therefore removed, and the bones could then be replaced with great facility, the outer toes resuming their normal position almost spontaneously. The wound in the integuments healed, and at the end of seven weeks he was able to return to his duty, the great toe, strange to say, having preserved all its movements. (*Malgaigne*, t. ii. p. 1095.)

Dislocation of the phalanges of the toes may occasionally occur, but from their diminutive size, and the mobility of the metatarso-phalangeal articulations, such an accident is very unlikely. The treatment required would be the same as in the fingers.]

James R. Lane.

DISTICHIA, or **DISTICHIASIS** (from *δῖς*, twice, and *στῖχος*, a row). A double row of eyelashes, the innermost ones of which irritate the eye. The pseudo-cilia, which grow in distichiasis, seldom occupy the whole length of the eyelid; but are mostly scattered about between the natural place of the cilia and the Meibomian apertures. (See **TRICHIASIS**.)

DURA MATER, FUNGOUS TUMORS OF. The disease arises gradually, in the form of a tumor, which makes its way through the bones of the cranium, and insensibly blends itself with the integuments, which seem, as it were, to make a part of it. Fungous tumors of the dura mater may originate spontaneously at any part of this membrane; but they are particularly apt to grow on the surface, which is adherent to the upper part of the skull, or to its basis. They are firm, indolent, and chronic, seeming as if they were the consequence of slow inflammation, affecting the vessels, which supply the dura mater, and inosculate with those of the diploe. It is very difficult to determine whether the disease begins in the dura mater or the substance of the bone itself. The general belief, however, is that the bone is affected secondarily, and that the disorder originates in the dura mater. The patient, the subject of the first case related by *M. Louis*, imputed the complaint to a fall, which he had met with four or five months previously, and in which the head itself had not received any violence; but, from this time, he experienced a stunning sensation, which continued till he died. The cranium and dura mater were found both equally diseased. Though this case may tend to prove that fungous tumors of the dura mater may form spontaneously, yet, it is not the less confirmed by a vast number of cases, that this affection more frequently follows blows on the head, than any other cause. Hence, a slow kind of thickening of the dura mater is produced, which ends in a sarcomatous excrescence, the formation of which always precedes the destruction of the bone. In the memoir, published by *M. Louis* in the fifth volume, 4to. of those of the Royal Academy of Surgery, there is a very interesting case, illustrating the nature of the present disease.

The subject was a young man, aged twenty-one, who had a considerable tumor on the left side of the head, which was taken for a *hernia cerebri*. (See *this Article*.) The swelling had begun in the region of the temple, and had gradually acquired the magnitude of a second head. The external ear was displaced by it, and pushed down as low as the angle of the lower jaw. At the upper part of the circumference of the base of the tumor, the inequalities of the perforated bone, and the pulsations of the brain, could be distinctly felt. Some parts of the mass were elastic and hard; others soft and fluctuating. A plaster, which had been applied, brought on a suppuration at some points, from which an ichorous matter was discharged. Shiverings and febrile symptoms ensued, and the man died in less than four months, in the year 1764. On dissection, a sarcomatous tumor of the dura mater was detected, together with the destruction of the whole portion of the skull, corresponding to the extent of the disease.

When a tumor of this nature has decidedly

formed, it makes its way outward through all the parts, soft or hard, which are opposed to it. The swelling, in becoming circumscribed, is partly blended with the dura mater, and its pressure produces an absorption of such parts of the skull as oppose its enlargement. It unexpectedly elevates itself externally, confounding itself with the scalp, and presents itself outwardly in the form of a preternatural, soft, yielding swelling, which even sometimes betrays an appearance of a decided fluctuation, or a pulsation, which may make it be mistaken for an aneurismal tumor. When once the swelling has made its exit from the cavity of the cranium, it expands on every side under the integuments, which readily make way for its growth. The scalp becomes distended, smooth, and œdematous over the extent of the tumor, and lastly, it ulcerates. The matter discharged from the ulcerations is thin and sanious: the outer part of the tumor is confounded with the integuments and edges of the skull, on which it rests, so that, in this state, it is easy to mistake the tumor for one whose base is altogether external. While the swelling thus increases in size externally, it also enlarges internally. The latter change takes place especially while the opening in the cranium is not large enough to admit the whole mass of the tumor, which then depresses the brain, and lodges in an excavation, which it forms for itself. But this cavity quickly diminishes, and becomes reduced almost to nothing, as soon as the tumor projects outwardly. The tables of the skull are absorbed to let the swelling arrive externally; but it is remarked, that the internal, or vitreous table, is always found much more extensively destroyed than the external one. Sometimes new bony matter is found deposited around the opening in the cranium.

It is asserted, that, whatever may be the situation of a fungous tumor of the dura mater, the outer layer of this membrane, upon which the disease forms, is alone altered, the inner layer and the pia mater being always unchanged. (*Lassus, Pathologie Chirurgicale*, tom. i. p. 501. éd. 1809.)

In one of these cases, detailed by Walther, the inner layer of the dura mater was quite natural, though one-half of the tumor, which was large, was within the skull, where it had formed for itself a deep excavation in the posterior lobe of the brain. And, what is remarkable, notwithstanding this latter change, the patient, the day before her death, retained all her intellectual faculties, and the power of voluntary motion. (*Journ. für Chirurgie von C. Graefe und Ph. v. Walther*, b. i. pp. 64, 65, 8vo. Berlin, 1820.)

According to surgical writers, fungous tumors of the dura mater have been caused by contusions on the skull, falls on the buttocks, concussions of the head or whole body, lues venerea, scrofula, inveterate rheumatism, &c. The three last of the alleged causes, however, seem to be little better than mere conjecture.

Even children of the most tender years are liable to the disease. M. Louis has related, that a child, two years of age, died of fungus of the dura mater, which had produced a swelling above the right ear, attended with a destruction of a portion of the parietal and temporal bones. (*Mém. de l'Acad. de Chirurgie*, tom. v. 4to. p. 31.)

Though the common opinion is, that these fungi grow entirely from the dura mater, Sandifort

asserts, that the vessels of the diploe have a considerable share in their production. (*Descriptio Musei Anat. Acad. Lugd. t. i. p. 152.*)

A similar belief was entertained by Heister and Kaufmann, and is espoused by Siebold and Walther, the latter imputing the disease to a simultaneous affection of the vessels of the dura mater, and pericranium, attended with an absorption of the earthy part of the bone. (*Journ. für Chir. von C. Graefe, &c. p. 91—93.*) M. Chelius has written an essay, in which a distinction is established between tumors commencing in the bone, and others beginning in the dura mater itself. (See *Archives de Méd. Mars, 1832.*)

The existence of a fungous tumor of the dura mater cannot be ascertained so long as there is no external change. The effects produced may originate from so many causes, that there would be great risk of a gross mistake in referring them to any particular ones. This is not the case when there is an opening in the skull. Then a hardness, felt from the very first at the circumference of the tumor, denotes that it comes from within. When the swelling is carefully handled, such a crackling sensation is perceived, as would arise from touching dry parchment stretched over the skin. On making much pressure, pain is occasioned, and sometimes a numbness in all the limbs, stupefaction and other more or less afflicting symptoms. The tumor in some measure returns inwards, especially, when not very large, and gradually rises up and outward again, when the pressure is discontinued. Sometimes there is pain; at other times there is none; which may be owing to the manner in which the tumor is affected by the edges of the bone through which it passes. The pain is often made to go off by compression, but returns as soon as this is taken off. The tumor has an alternate motion, derived from the pulsation of the brain, or of the large arteries at its base. This throbbing motion has led many practitioners to mistake the disease for an aneurism, as happened in the second case, related in the memoir of M. Louis. When the tumor is pushed sideways, and the finger carried between it and the edge of the bone, through which the disease protrudes, the bony edge may be felt, touching the base of the swelling, and more or less constricting it. This symptom, when distinguishable, added to a certain hardness and elasticity, and sometimes a facility of reduction, forms a pathognomonic mark, whereby fungous tumors of the dura mater may be discriminated from herniæ of the brain, external fleshy tumors, abscesses, exostosis, and other affections, which at first sight resemble them.

Probably, however, some variety prevails in different instances; for, in the cases recorded by Walther, there was no pulsation, strictly so called, but merely an obscure movement, or an alternate distension and flaccidity, arising from the influx of blood into the vessels of the diseased mass; the tumors could not be pushed within the cranium in the slightest degree; nor did the attempt cause any of the effects usually observed to proceed from pressure on the brain. No aperture could be felt in the skull, much less could the irregular edges of the bone around the tumor be distinguished. (*Journ. für Chir. b. i. p. 57—61, &c. 8vo. Berlin, 1820.*)

Whatever movements also were perceptible in

the swellings, Walther is convinced could not be communicated to them by the pulsations of the subjacent brain; because they were wedged, as it were, in an aperture in the skull, and adherent to the dura mater beneath them, and to the superincumbent periosteum; so that, even in the dead subject, they did not admit of being pushed in the least outwards without difficulty, and the employment of strong pressure. (Vol. cit. p. 57.)

Indeed, this tight constriction of the tumor not only explains why stupor, paralysis, &c. were not brought on in these particular examples by external pressure, but also why the edges of the hole in the skull could not be felt; and the small size of the same opening, in relation to the magnitude of the swelling, fully accounts, in my opinion, for the circumstance of the swelling not sinking inwards under pressure. But I am far from being convinced with Walther that fungi of the dura mater are in their nature always irreducible (see vol. cit. p. 82); a belief which he grounds upon the connection of the diseased mass with the vessels of the diploe, its constriction by the bone, and its expansion under as well as above the cranium. Here I think Walther is as wrong in saying that none of these fungi can possibly be reduced, as others would be in asserting that it is their invariable character to be reducible. These differences must chiefly depend upon the size of the swelling, in relation to that of the aperture in the skull.

Generally speaking, fungous tumors of the dura mater are very dangerous, as well on account of their nature as of the difficulty of curing them in any certain manner, and of the internal and external disorder which they may occasion. Such as have a pedicle, the base of which is not extensive, which are firm in their texture without much disease in the surrounding bone, are movable, not very painful, and, in persons who are in other respects quite well, are in general reputed to be the least perilous. These are the cases in which a cure may be attempted with a hope of success, though the event is always exceedingly doubtful.

When the contrary of what has been just related occurs—when the disease is of long continuance, and the brain already affected—nothing favourable can be expected.

Compression is the most simple remedial means, and has naturally occurred to such practitioners as have mistaken the disease for an aneurism, or a hernia cerebri. The efficacy of this method has been further misconceived, because the tumor, when not very large, has sometimes been partly or even wholly reduced, without any bad consequences. This had no little share in leading to errors concerning the true character of the disease. But, as might be conceived, this reduction only being attended with temporary success, and having no effect whatever on the original cause of the affection, the symptoms returned, and the tumor rose up again the moment the compression was discontinued. There is a fact in the memoir of M. Louis which seems to evince that good effects may sometimes be produced by compression judiciously employed. A woman, brought to the brink of the grave by the symptoms occasioned by a tumor of the above kind, having rested with her head for some time on the same side as the tumor, found the swelling so suddenly reduced, without any ill effects, that she thought herself cured by

some miracle. Compression, artfully kept up by means of a piece of tin fastened to her cap, prevented the protrusion of the tumor again. The pressure, however, not having been always very exact, the symptoms every now and then recurred, while the tumor was in the act of being depressed again, and they afterwards ceased, on the swelling having assumed a suitable position. The symptoms were, doubtless, occasioned by the irritation which the tumor suffered in passing the inequalities around the opening through which it protruded. The patient lived in this state nine years, having every now and then fits of insensibility, in one of which, attended with hiccough and vomiting, she perished.

[These cases of fungous tumors of the dura mater are, for the most part, of a malignant character, and do not admit of operative procedure either by the knife or by escharotics. The surgeon's skill will be best shown in determining, in each individual case, whether the growth be of an innocent nature or not. The following directions, given by Mr. Cooper for their removal, will only apply to the comparatively few cases in which the operator can feel assured of the non-malignancy of the growth he has to deal with; and even in such cases it is more than doubtful whether the dura mater should be so extensively interfered with as Mr. Cooper suggests.]

As compression cannot be depended upon, the following safer method may be tried:—It consists in exposing the tumor with a knife, which is certainly preferable to caustics, the action of which is very tedious and painful, and can never be limited or extended with any degree of precision. A crucial incision may be made through the scalp covering the tumor, and the flaps dissected up, and reflected, so as to bring all the bony circumference into view. Then with trephines repeatedly applied, or with (what would be better) Mr. Hey's saws, all the margin of the bone should be carefully removed. Now, if it be true that the vessels of the diploe are chiefly concerned in the supply of the diseased mass, we see that this source of its growth must be destroyed by the foregoing proceeding.

The tumor, thus disengaged on all sides, may be cut off with a scalpel; and such arteries as bleed much should be tied. Then, instead of applying caustic, as sometimes advised, perhaps it would be better to remove every part of both layers of the dura mater immediately under the situation of the excrescence. By this means, and the removal of the surrounding bone and diploe, all chance of the regeneration of the tumor would be prevented. In attempting the excision of a fungus of the dura mater, it is certainly an interesting point to know whether the tumor has an intimate vascular connection with the diploe and pericranium, as asserted by Siebold, Walther, and some other respectable authorities, though the importance of the information on this subject to the practitioner is somewhat lessened by his being aware that it is necessary always to begin with sawing away the bone in the immediate vicinity of the diseased mass. In the dissection of one case, Walther found the pericranium thickened for a considerable extent around the disease, and closely connected with the tumor by vessels. (Vol. cit. p. 100.)

When the tumor is sarcomatous, and its pedi-

cle small and narrow, as sometimes happens, one should not hesitate to cut it off.

This method is preferable to tying its base with a ligature; a plan which could not be executed without dragging and seriously injuring the dura mater; and the fatal effects of which I saw exemplified in one case that occurred many years ago in St. Bartholomew's Hospital, and was operated upon by the late Mr. Ramsden. Excision is also preferable to caustics, which cause great pain, and very often convulsions. In performing the extirpation, we should remove the whole extent of the tumor, and, if possible, its root, even though it may extend as deeply as the internal layer of the dura mater. This step must not be delayed, for the disease will continue to increase, so as to affect the brain, become incurable, and even mortal. It is to such decision that we must impute the success which attended the treatment of the Spaniard Avalos, of whom Marcus Aurelius Severinus makes mention. The above nobleman was afflicted with intolerable headaches, which no remedy could appease. It was proposed to him to trepan the cranium, an operation to which he consented. This proceeding brought into view, under the bone, a fungous excrescence, the destruction of which proved a permanent cure of the violent pains, which the disease had occasioned. It is not mentioned in this case whether the internal layer of the dura mater was healthy or not; but there is foundation for believing, that if the extirpation of these tumors be undertaken in time, and bold measures be pursued, as in the instance just cited, success would often be obtained. Indeed, reason would support this opinion; for, when the disease is not extensive, it is necessary to expose a much smaller surface of the dura mater.

It appears to me, however, that trepanning can never be warrantable, unless the disease be indicated by some external changes. I saw my late

master, Mr. Ramsden, trepan a man for a mere fixed pain in one part of the head, on the supposition, that there was a tumor under the bone; but no tumor was found, and the operation caused inflammation of the dura mater, and proved fatal.

No doubt, in some cases, the hæmorrhage will be considerable, as was exemplified in the instance in which Walther made an incision at the base of one of these fungi, in order to ascertain its nature: two pints of blood being lost from several vessels of large size ere they could be secured; and the further use of the knife discontinued.

M. Louis has described other tumors, which grow from the surface of the dura mater, when this membrane has been denuded, as after the application of the trephine. They only seem to differ from the preceding in not existing before the opening was made in the skull. Tumors of the dura mater should not be confounded with hernia cerebri. (See *this Article*.)

DYNAMOMETER. An instrument, employed by M. Malgaigne for measuring the degree of extension made with pulleys in the reduction of dislocations. (See *Mém. de l'Acad. R. de Méd.* t. v. p. 143.) It will serve also to measure the force exerted in lithotripsy.

E

EAR, DISEASES OF. An organ, so valuable and necessary to the perfection of our existence, as the ear, should have all the resources of surgery exerted for the preservation of its integrity, and the removal of the diseases, with which it may be affected. What, indeed, would have been our lot, if nature had been less liberal, and not endued us with the sense of hearing? As Leschevin has observed, we should then have been ill qualified for the receipt of instruction; a principal inlet of divine and human knowledge would have been closed; and there being no reciprocal communication of ideas, our feeble reason could never have approached perfection. Even our life itself, being as it were dependent upon all such bodies as surround us, would have been incessantly exposed to dangers. The eyesight serves to render us conscious of objects which present themselves before us, and, when we judge them to be hurtful, we endeavour to avoid them. But, to say nothing of our inability to look on all sides at once, our eyes become of no service to us, whenever we happen to be enveloped in darkness. The hearing is then the only sense that watches over our safety. It warns us, not only of every thing which is moving about us, but

likewise of noises which are more or less distant. Such are the inestimable advantages, which we derive from this organ. Its importance, when healthy, makes it worthy of the utmost efforts of surgery, when diseased. (See *Méd. sur les Sujets proposés pour le Prix de l'Acad. Royal de Chirurgie*, t. ix. pp. 111, 112, ed. 12mo.)

It is not many years since the diseases of the ear were a subject, on which the greatest ignorance and the most mistaken opinions prevailed; and, indeed, how could any correct pathological information be expected, while anatomists had not given a complete and accurate description of the organ itself? Also, notwithstanding what has now been made out respecting disorders of the ear, and that within the last twelve or sixteen years the knowledge of them has nearly equalled that of the eye, it is generally admitted that they still require much further investigation. Though Duverney, Valsalva, Morgagni, &c. dispelled some of the darkness which covered this branch of surgery, they left a great deal undone. Since their time, science has been enriched with the valuable discoveries of Cotunni, Meckel, Scarpa, and Comparetti; the two first of whom demonstrated that the labyrinth is filled with a limpid fluid, and not

(as was pretended) with confined air; while the last two distinguished anatomists favoured the public with the first very accurate description of the parts composing the labyrinth, especially the semicircular canals.

In 1763, the French Academy of Surgery offered a prize for the best essay on diseases of the ear, and two years afterwards, the honour was adjudged to that of Leschevin, senior surgeon of the hospital at Rouen. This memoir is still of great value, few modern treatises being more complete. The most useful contributors to our stock of information on the pathology of the ear, subsequently to M. Leschevin, have been Ritter, and Lenten (*Ueber das schwere Gehör*, Leipz. 1794); Trampel (*Arnemann's Magaz.* b. ii. 1798); Pfingsten (*Vieljährige Erfahrung ueber die Gehörfehler*, Kiel, 1802); Alard (*Sur le Catarrhe de l'Oreille*, 8vo. Paris, 1807, edit. 2); Sir A. Cooper (*Phil. Trans.* 1802); Portal (*Anat. Méd.* 1803); J. C. Saunders (*Anat. and Dis. of the Ear*, 1806); Boyer (*Mal. Chir.* t. vi.); Itard (*Traité des Mal. de l'Oreille*, 8vo. 2 tomes); Saissy, in an essay, which received the approbation of the Medical Society of Bordeaux; Rosenthal in a short, but sensible tract on the pathology of the ear (see *Journ. Complém.* t. vi. 1820); and Krämer in a treatise recently published. [The works of Mr. Pilcher, *the Anatomy, Economy, and Diseases of the Ear*; that of Mr. Wilde, *Aural Surgery*; and of Mr. Toynbee, *the Diseases of the Ear, their Nature, Diagnosis, and Treatment*, have added much to our knowledge of aural pathology and surgery.]

Notwithstanding the laudable endeavours of so many men of eminence, the pathology of the internal ear, and the treatment of its diseases, are far, I may say, very far from a high state of improvement. To further advances, indeed, some discouraging obstacles present themselves: the auditory apparatus is extremely complicated; the most important parts of it are entirely out of the reach of ocular inspection: the anatomy of the organ is perhaps not yet completely unravelled; the exact uses and action of several parts of it, anatomically known, are still involved in mystery; the opportunities of dissecting the ear in a state of disease are neither frequent, nor duly watched; and even when they are taken, and when vestiges of disease or imperfection are traced to particular parts of the organ, the utmost difficulty is experienced in drawing any useful practical conclusion, because the natural uses of those parts, and the precise manner in which they contribute to the perfection of the ear, are not known to the most enlightened physiologists. We are here nearly in the same helpless dilemma as a watchmaker would be, were he in examining the interior of a watch, to find parts broken and out of order, the exact uses of which, in the perfection of the instrument, he had not first studied and comprehended. In fact, the physiology of the ear is but imperfectly understood; and, as Rosenthal remarks (*Journ. Complém.* t. vi. p. 17), if, notwithstanding the progress made in optics, and the complete knowledge of the structure of the eye, a perfect explanation has not yet been given of the phenomena of this organ, as an instrument of vision, we cannot wonder, that with far more circumscribed information about acoustics, and the greater difficulty of unravelling the structure of the ear, so little progress should have been

made in the physiology of the latter organ. Were it practicable in acoustics to arrive at that precision and certainty, which would enable us to establish laws in the theory of sound, as fixed as those which relate to light, this void in physiological science might perhaps be obviated. But Rosenthal justly argues, that hitherto the approach to perfection has not been made, and this notwithstanding the learned and valuable labours of Culdain. (*Akustik.* 4to. Leipz. 1802.) Some facts, however, are admitted to be well ascertained, and the researches of Autenrieth and Kerner (*Reil's Archiv. für die Physiol.* t. ix. pp. 313—376) are honourably mentioned; for, though they only elucidate the function of the conducting part of the ear, they are of unquestionable importance to the medical practitioner. It is clearly proved, that the difference in the length and breadth of the meatus auditorius, the form of the membrana tympani, and the make of the cavity of the tympanum, modify sound; that is to say, that the differences of structure of the auricle and meatus auditorius externus, which merely receive and concentrate the sonorous undulations, as these emanate from a vibrating body, can only influence the degree of force, or weakness of the sound; while, on the contrary, the differences of structure in the membrane and cavity of the tympanum are not limited to this effect, but the greater or less tension of the one, and the more or less considerable capacity of the other, appear to alter in a greater or lesser degree the particular character of the sound. (*Journal Complém.* t. vi. p. 20.) [We would gladly make honourable mention also of Sir John Herschel and Mr. Wheatstone, whose elucidations of the doctrine of sound are likely to throw light upon the physiology of hearing.]

1. Wounds and Defects of the external Ear.

The external ear, which is a sort of instrument calculated for concentrating the undulations or waves of sound, may be totally cut off, without deafness being the consequence. For a few days after the loss, the hearing is rather hard; but the infirmity gradually diminishes, the increased sensibility of the auditory nerve compensating for the imperfection of the organic apparatus. (*Richerand, Nosogr. Chir.* t. ii. p. 122, éd. 2.)

Dr. Hennen says, that he has met with a case where the external ear was completely removed by a cannon-shot, and yet the sense of hearing was as acute as ever. (*Principles of Military Surgery*, p. 348, ed. 2.) Another case, recorded by Wepfer, also proves, that a total loss of the auricle may not cause any material injury of hearing, for the patient of whom he speaks had had the whole of the external ear destroyed by ulceration, and yet could hear as well as before the loss. (*Kritter und Lentin über das schwere Gehör*, p. 19, Leipz. 1794.) [Mr. Toynbee gives a case in which the watch was heard at a normal distance on both sides after the removal of the ears.] However, if we are to credit the statement of other writers, the recovery is generally far less complete. Thus Leschevin notices, that they who have lost the external ear, or have it naturally too flat, or ill-shaped, have the hearing less fine. The defect can only be remedied by an artificial ear, or an ear-trumpet, which, receiving a large quantity of the sonorous undulations, and directing them towards the meatus auditorius, thus

does the office of the external ear. (*Prix de l'Acad. Royale de Chir.* t. ix. p. 120, edit. 12mo.)

Wounds are not the only causes by which the external ear may be lost: its separation is sometimes the consequence of ulceration, and sometimes the effect of the bites of horses and other animals. In cold climates, it is frequently frozen, and afterwards attacked with inflammation and sloughing. When the external ear is not totally separated from the head, the surgeon should not despair of being able to accomplish the reunion of it. This attempt should always be made, however small a connection the part may have with the skin; for, in wounds of this kind, the efforts of surgery have occasionally succeeded beyond all expectation.

Wounds of the external ear, whatever may be their size and shape, do not require different treatment from that of the generality of other wounds. The reunion of the divided part is the only indication, and it may be in most instances easily fulfilled by means of methodical dressings. Such writers as have recommended sutures for wounds of the ear (says Leschevin), have founded this advice upon the difficulty of applying to the part a bandage, that will keep the edges of the wound exactly together. The cranium, however, affords a firm and equal surface, against which the external ear may be conveniently fixed. Certainly, it is not more easy to secure dressings on the nose than on the ear; and yet cases are recorded, in which the cartilaginous part of the nose was wounded, and almost entirely separated, and the union was effected without the aid of sutures. (See *Mém. de M. Pibrac sur l'Abus des Sutures*, in *Mém. de l'Acad. de Chir.* tom. iii.)

In wounds of the ear, then, we may conclude that sutures are generally useless and unnecessary. As examples may occur, however, in which the wound may be so irregular and considerable as not to admit of being accurately united, except by this means, it should not be absolutely rejected. An enlightened surgeon will not abandon altogether any curative plans; he only points out their proper utility, and keeps them within their right limits. When sticking plaster, simple dressings, and a bandage that makes moderate pressure, appear insufficient for keeping the edges of a wound of the ear in due contact, the judicious practitioner will not hesitate to employ sutures.

When a bandage is applied to the external ear, it should only be put on with moderate tightness, since much pressure gives considerable uneasiness, and may induce sloughing. In order to prevent these disagreeable effects, Leschevin advises us to fill the space behind the ear with soft wool or cotton, against which the part may be compressed without risk. (*Op. cit.* p. 119.)

Baron Boyer remembers a medical student, who was compelled by an ulcer on the sacrum to lie for a long time on his side, in which posture the pressure on the ear caused a slough of the antihelix, and after the separation of the dead part, an aperture, large enough to receive the end of the little finger, was left in the pinna or auricle.

In the application of sutures to the ear, the ancients caution us to avoid carefully the cartilage, and to sew only the skin. They were fearful, that pricking the cartilage would make it mortify, "*ce qui est souvent fois arrivé*," says Paré. But, notwithstanding so respectable an authority, as Leschevin has remarked, the moderns make no scruple

about sewing cartilages. In wounds of the nose, Verduc expressly directs the skin and cartilage to be pierced at once, and the success of the plan is put out of all doubt by a multitude of facts. The same treatment may also be safely extended to the ear.

In this section, a few malformations of the external ear require notice. Sometimes the orifice of the meatus auditorius is diminished by the tragus, antitragus, and antihelix being depressed into it. Here the excision of these wrongly formed eminences has been recommended, as a surer means of perfecting the sense of hearing, than the use of any tube, or dilating instruments. The tragus has been known to project considerably backwards, and to apply itself most closely over the orifice of the meatus, which was also a mere slit, instead of a round opening. In one case of this description, relief was obtained by the introduction of tubes, calculated to maintain the tragus in its proper position. (*Dict. des Sciences Méd.* t. xxxviii. p. 28.)

Sometimes the outer ear is entirely wanting. Thus Fritelli has given an account of a child in this condition, whose physiognomy at the same time strongly resembled that of an ape. (*Orteschi Giorn. di Med.* t. iii. p. 80.) Oberteuffer has also recorded an example of a total deficiency of the auricles in an adult, who yet heard very well. (*Stark's Neues Archiv.* b. ii. p. 638. *J. F. Meckel, Handbuch der Pathol. Anat.* b. i. p. 400. Leipz. 1812.)

I remember a child, which was exhibited many years ago in London, as a curiosity; it was entirely destitute of external ears, and no vestiges of the meatus auditorii could be seen, these openings being completely covered by the common integuments. Yet the child could hear a great deal, though the sense was certainly dull and imperfect. I recollect, that the circumstance of the patient hearing so well as he did, was what excited considerable surprise. I do not recollect, however, at the present time, the degree in which this sense was enjoyed, and several other circumstances, such as the child's age, power of speech, &c. The example is interesting, inasmuch as it proves, that even a deficiency of the auricles, combined with an imperforate condition of both ears, may be unattended with complete deafness, provided the internal and more essential parts of these organs are sound and perfectly formed.

Baron Boyer attended a young man, the lobule of one of whose ears extended in a very inconvenient manner over the cheek: the redundant portion was removed with a pair of scissors, and the wound soon healed. [Less important malformations, as of the helix and antihelix, and of the tragus and antitragus, not interfering with the opening into the meatus, are of frequent occurrence, but do not require treatment.]

The auricle, not being a very irritable part, is not often inflamed, and when it is so, the affection is generally of an erysipelatous character. Portal has seen the part nearly an inch thick; and he takes notice of the prodigious thickness which the lobe of the ear sometimes acquires in women who wear heavy ear-rings, which keep up constant irritation. Small encysted and adipose swellings occasionally grow under the skin of the external ear, and demand the same treatment as swellings of the same nature in other situations. (See

TUMORS.) Lastly, the external ear is frequently the seat of scrofulous and other ill-conditioned ulcers. These cases generally require cleanliness, alterative medicines, and to be dressed with the ung. zinci, or the ung. hydrarg. nitrat., or a solution of the nitrate of silver; and sometimes, when the sores resist for a long time the effects of medicine and the usual dressings, they will soon heal up, if the treatment be assisted with a blister, or seton, kept open on the nape of the neck. (See *Dict. des Sciences Méd.* t. xxxviii. pp. 28, 29.) [The auricle is especially prone to attacks of exanthematous disease, both acute and chronic, and more particularly to the eruptions of scarlet fever and small pox, and to herpes and psoriasis; all of which are liable to extend along the auditory canal, and to implicate the membrana tympani.]

2. Of the Meatus Auditorius, and its Imperfections.

This is the passage, which leads from the cavity of the external ear, called the concha, down to the membrane of the tympanum. It is partly cartilaginous and partly bony, and has an oblique and curved direction, so that its whole extent cannot be easily seen. There are circumstances, however, in which it is proper to look as far as possible into the passage. Such is the case, when the surgeon is to extract any foreign body, to remove an excrescence, or to detect any other occasion of deafness; [but above all, to ascertain the condition of the membrane of the tympanum, and of the cavity itself when the membrane is ulcerated.] Fabricius Hildanus gives a piece of advice upon this subject, not to be despised; namely, to expose the ear to the rays of the sun, in order to be enabled to see the very bottom of the passage.

[As sunlight cannot always be obtained it is desirable to use artificial light. For this purpose the portable lamp made by Miller, or the gas lamp made by Weiss, may be used. For the purpose of straightening the external meatus, and of conducting inwards the rays of light, a speculum must be used. The most efficient is the tubular ear speculum, oval at its small extremity.]

The surgical operations practised on the meatus auditorius, are confined to opening it, when preternaturally closed, extracting foreign bodies, washing the passage out with injections, removing excrescences, opening abscesses, &c. &c.

The case which we shall next treat of, is the imperforation of the meatus auditorius externus, a defect with which some children are born.

When the malformation exists in both ears, it generally renders the subject dumb, as well as deaf, for, as he is incapable of imitating sounds, which he does not hear, he cannot of course learn to speak, although the organs of speech may be perfect, and in every respect rightly disposed. In this case, the surgeon has to rectify the error of nature, and (to use the language of Leschevin) he has to give, by a double miracle, hearing and speech to an animated being, who, deprived of these two faculties, can scarcely be regarded in society as one of the human race. How highly must such an operation raise the utility and excellence of surgery in the estimation of the world!

When the meatus auditorius externus is merely closed by an external membrane, the nature of the case is evident, and the mode of relief equally easy. But, when the membrane is more deeply situated

in the passage, near the tympanum, the diagnosis is attended with increased difficulty, and the treatment with greater trouble.

If the preternatural membrane be external, or only a little way within the passage, it is to be divided with a bistoury; the small flaps are to be cut away; a tent, of a suitable size, is to be introduced into the opening; and the wound is to be healed *secundum artem*, care being taken to keep it constantly dilated, until the cicatrization is completed.

When the obstruction is deeply situated, we must first be sure of its existence, which is never ascertained, or even suspected, till after a long while. It is not till after children are past the age at which they usually begin to talk, that any defect is suspected in the organ of hearing, because, until this period, little notice is taken, whether they hear or not. As soon as it is clear that this sense is deficient, the ears should always be examined with great attention, in order to discover, if possible, the cause of deafness. Sometimes, the infirmity depends upon a malformation of the internal ear, and the cause does not then admit of detection. The most convenient method of making the examination is to expose the ear, which is about to be examined, to the light of the sun. In this situation, the surgeon will be able to see beyond the middle of the bony part of the meatus, if he places his eye opposite the orifice of the passage, and takes care to efface the curvature of the cartilaginous portion of the canal, by drawing upward the external ear. If the passage has been carefully cleansed before the examination, the skin forming the obstruction, may now be seen, unless it be immediately adherent to the membrana tympani.

When the preternatural septum is not closely united to the tympanum, its destruction should be attempted, and hopes of effecting the object, either suddenly or gradually, may reasonably be entertained. According to Leschevin, the particular situation of the obstruction is the circumstance, by which the surgeon ought to be guided in making a choice of the means for this operation. If the membranous partition is so far from the tympanum, that it can be pierced without danger of wounding the latter part, there can be no hesitation in choosing the plan to be adopted. In the contrary state of things, Leschevin is an advocate for the employment of caustic, not only on account of the risk of injuring the tympanum with a cutting instrument, but, also because, if the puncture were ever so well executed, a tent could not be introduced into it, so as to prevent it from closing again.

In the first case, a very narrow sharp-pointed bistoury should be used: after its blade has been wrapped round with a bit of tape to within a line of the point, it is to be passed perpendicularly down to the preternatural membrane, which is to be cut through its whole diameter. The instrument being then directed first towards one side, then the other, the crucial incision is to be completed. As the flaps, which are small and deeply situated, cannot be removed, the surgeon must be content with keeping them separated by means of a blunt tent. The wound will heal just as favourably as that occasioned in removing the imperforation of the concha, or outer part of the meatus auditorius. (*Prix de l'Acad. de Chir.* pp. 124—126,

t. ix.) In the second case, that is to say, when the risk of wounding the membrana tympani leads us to prefer the employment of caustic, the safest and most commodious way of putting the plan into execution would be that of touching the obstruction, as often as circumstance may require, with the extremity of a bougie armed with nitrate of silver. In the intervals of the applications, no dressings need be introduced, except a bit of clean soft cotton, for the purpose of absorbing any discharge which may take place within the passage.

It is manifest, that if the whole, or a considerable part of the meatus auditorius externus were wanting, the foregoing measures would be insufficient. The following observations of Leschevin merit attention: — "I do not here allude to cases, in which a malformation of the bone exists. I know not, whether there are any examples of such an imperforation; but, it is clear, that it would be absolutely incurable. I speak of a temporal bone perfectly formed in all its parts, and the meatus auditorius of which, instead of being merely lined by a membrane, as in the natural state, is blocked up by the cohesion of the parietes of this membrane throughout a certain extent of the canal; just as the urethra, rectum, or vagina, is sometimes observed to be not simply closed by a membrane, but by a true obliteration of its cavity.

"Such a defect in the ear may be congenital, and it may also arise from a wound, or ulceration, of the whole circumference of the meatus auditorius externus, this canal having become closed by the adhesion of its parietes, on cicatrisation taking place.

"Such an imperforation, whether congenital or accidental, must certainly be more difficult to cure than the examples treated of above; but," says Leschevin, "I do not for this reason believe, that the case ought to be entirely abandoned. Yet, I would not have the cure attempted in all sorts of circumstances. For instance, if the defect only existed in one ear, and the other were sound, I would not undertake the operation, because, as the patient could hear tolerably well on one side, the advantages which he might derive from having the enjoyment of the other ear, would not counterbalance the pain and bad symptoms occasioned by such an experiment, the success of which is extremely uncertain. I would not then run the risk of making a perforation, except in a case of complete deafness; and I propose this means only as a dubious one, upon the fundamental maxim, so often laid down, that it is preferable to employ a doubtful remedy, than none at all.

"With respect to the mode of executing this operation," says Leschevin, "the trocar seems the most eligible instrument. I would employ one that is very short, and the point of which is bluntyish, and only projects out of a canula as little as possible. This construction would indeed make the instrument less adapted to pierce any thing; but, still, as the parts to be perforated are firm, their division might be accomplished sufficiently well; and the inconvenience of a trivial difficulty in the introduction of the trocar is comparatively much less than that which would attend the danger of wounding with a sharper point the membrane of the tympanum. I would plunge the point of the instrument into the place, where the opening of the meatus auditorius externally ought naturally to be, and which would be denoted, either by a

slight depression, or at all events by attending to the different parts of the ear, especially the tragus, which is situated directly over this passage. I would push in the trocar gently, in the direction of the canal formed in the bone, until the point of the instrument felt as if it had reached a vacant space. Then, withdrawing the trocar, and leaving the canula, I would try whether the patient could hear. I would then introduce into the cavity of the canula itself a small, rather firm tent, of the length of the passage, or a small bougie. By means of a probe, I would push it to the end of the canula, which I would now take out, observing to press upon the tent, which is to be left in. The rest of the treatment consists in keeping the canal pervious, making it suppurate, and healing it with common applications. One essential caution, however, would be that of keeping the part dilated long after it had healed: otherwise, it might close again, and a repetition of the operation become necessary. This happened to Heister, as he himself apprises us, and it occurred to Roonhuysen in treating imperforations of the vagina.

"If the cohesion of the parietes of the meatus auditorius externus were to extend to the membrana tympani inclusively, the operation would be fruitless; but, as it is impossible to ascertain this circumstance before the attempt is made, the surgeon would incur no disgrace by relinquishing the operation, and giving up the treatment of an incurable disease. If, then, after the trocar were introduced to about the depth of the tympanum, the situation of which must be judged of by our anatomical knowledge, no cavity were met with, the operation should be abandoned; and if, in these circumstances, any one were to impute the want of success to the inefficacy of surgery, or the unskilfulness of the surgeon, he would act very unfairly.

"It is also plain, that such an operation could cure a congenital deafness, only inasmuch as it might depend upon the imperforation; for, if there should exist, at the same time, in the internal ear, any malformation, destructive of the power of the organ, the remedying of the external defect would be quite useless." (*Leschevin, in Prix de l'Acad. de Chirurgie*, tom. ix. pp. 127—132.)

We find, that this author entertains a great dread of wounding the membrana tympani, and certainly he is right in generally insisting upon the prudence of avoiding such an accident. It will appear, however, in the sequel of this article, that under certain circumstances puncturing the tympanum has been successfully practised as a mode of remedying deafness. The operation, however, demands caution; for, if done so as to injure the connection of the malleus with the membrana tympani, the hearing must ever afterwards be very imperfect. [More extensive acquaintance with ear diseases shows that the above-named malformations are of rare occurrence; and that when they do take place are generally met with at the outer part of the canal, and consequently within reach of easy treatment: this circumstance is to be expected in the foetal and infantile life, from the superficial position of the membrana tympani, and the shortness of the canal, which, lengthening in the progress of development carries the cuticular lining with it. But a more important malformation, pointed out by Mr. Toynbee, is oc-

casional met with in the osseous part of the canal, arising from enlargements from the bone; these, however, are growths occurring at any interval after birth; they may be one or several from opposite surfaces of the meatus auditorius, more or less near to, or even in contact with the membrane; but the writer has not yet positively known them to encroach upon the cavity of the tympanum. The skin covering them is bright, polished, vascular, and dry, the result of distention. The interspace between these exostoses usually admits the sonorous waves, and then the sense of hearing is little or not at all impeded; but the small aperture is so likely to be occupied by cerumen and other secretions from the canal, that deafness is a frequent result; further, the bony growths may become so firmly approximated as to totally close the tube. These tumors may be diminished by the use of iodine locally and generally, and no operation for their removal must be attempted.]

3. *Unusual Smallness of the Meatus Auditorius Externus.*

Imperforation is not the only congenital imperfection of the meatus auditorius; this passage is occasionally too narrow for the admission of a due quantity of the sonorous undulations, and the sense is of course weakened. Leschevin mentions that M. de la Metrie found this canal so narrow in a young person, that it could hardly admit a probe. What has been observed concerning the imperforation, is also applicable to this case. If it depends upon malformation of the bone, it is manifestly incurable; but, if it is owing to a thickening of the soft parts within the meatus, hopes may be indulged of doing good by gradually dilating the passage with tents, which should be increased in size from time to time, and, lastly, making the patient wear, for a considerable time, a tube, adapted to the part in shape. (*Leschevin, in Prix de l'Acad. de Chirurgie, t. ix. p. 132.*)

Mr. Earle has published a case, in which the diameter of the meatus auditorius was considerably lessened by a thickening of the surrounding parts, and especially of the cuticle, attended with a discharge from the passage, and great impairment of hearing. A cure was effected by injecting into the passage a very strong solution of the nitrate of silver, which, in a few days, was followed by a detachment of the thickened portions of cuticle. This evacuation was assisted by throwing warm water into the passage. (See *Med. Chir. Trans. vol. x. p. 411, &c.*) Boyer was consulted for a deafness, arising from a malformation, which consisted of a flattening of the meatus, its opposite sides being for some extent in contact. The patient was advised to wear in the ear a gold tube of suitable shape, by which means he was enabled to hear perfectly well. [It must be confessed that such congenital defects rarely fall under treatment, but acquired narrowness of the canal, that consequent upon chronic inflammation, of various characters, is not at all infrequent; but the hearing power is not diminished thereby.]

4. *Faulty Shape of the Meatus Auditorius Externus.*

Anatomy informs us, that this passage is naturally oblique, and somewhat winding; and natural philosophy teaches us the necessity of such obli-

quity, which multiplies the reflections of the sonorous waves, and thereby strengthens the sense. This theory, says Leschevin, is confirmed by experience; for, there are persons, in whom the meatus auditorius is almost straight, and they are found to be hard of hearing. If there is any means of correcting this defect, it must be that of substituting, for the natural curvature of the passage, a curved and conical tube, which must be placed at the outside of the organ, just like a hearing trumpet. The acoustic instrument, invented by Deckers, which is much more convenient, might also prove useful. (*Op. cit. p. 133.*)

[Experience readily teaches us, however, that such defects occur without producing inconvenience, at least that is to be appreciated; it most probably happens that the deficiency in hearing is supplied by an exaltation in function of the auditory nerve, occurring at an age before the defect is perceived.]

5. *Extraneous Substances, Insects, &c., in the Meatus Auditorius Externus.*

Foreign bodies met with in this situation are inert substances, which have been introduced by some external force; insects, which have insinuated themselves into the passage; or the cerumen itself, hardened in such a degree, as to obstruct the transmission of the sonorous undulations. Worms, which make their appearance in the meatus auditorius, are always produced subsequently to ulcerations in the passage, or in the interior of the tympanum, and very often such insects are quite unsuspected causes of particular symptoms. In the cases of surgery, published in 1778, by Acrel, there is an instance confirming the statement just offered. It is the case of a woman, who, having been long afflicted with a hardness of hearing, was suddenly seized with violent convulsions, without any apparent cause, and soon afterwards complained of an acute pain in the ear. This affection was followed by a recurrence of convulsions, which were still more vehement. A small tent of fine linen, moistened with a mixture of oil and laudanum, was introduced into the meatus auditorius, and, on removing it the next day, several small round worms were observed upon it, and from that period all the symptoms disappeared. To this case, we shall add another from Morgagni:—A young woman consulted Valsalva, and told him, that when she was a girl, a worm had been discharged from her left ear; that another one, about six months ago, had also been discharged, very much like a small silkworm in shape. This event took place after very acute pain in the same ear, the forehead and temples. She added, that since this, she had been tormented with the same pains, at different intervals, and so severely, that she often swooned away for two hours together. On recovering from this state, a small worm was discharged, of the same shape as, but much smaller than, the preceding one, and she was now afflicted with deafness and insensibility on the same side. After hearing this relation, Valsalva no longer entertained any doubt of the membrane of the tympanum being ulcerated. He proposed the employment of an injection, in order to destroy such worms as yet remained. For this purpose, distilled water of St. John's wort, in which mercury had been agitated, was used. In order to prevent an occurrence of the inconvenience, Morgagni recommends the affected ear to be closed up when the patient goes to sleep, in autumn and

summer. If this be not done, flies, attracted by the suppuration, enter the meatus auditorius, and, while the patient is unconscious, deposit their eggs in the ear. Acrel, in speaking of worms, generated in the meatus auditorius, observes, that there is no better remedy for them than the decoction of *ledum palustre*, injected into the ear several times a day. However, as this plant cannot always be procured, an infusion of tobacco in oil of almonds may be used, a few drops of which are to be introduced into the ear, and retained there by means of a little bit of cotton. This application, which is not injurious to the lining of the passage, is fatal to insects, and especially to worms. When caterpillars, ants, earwigs, and other insects, have insinuated themselves into the meatus auditorius, they may be removed with a piece of lint, smeared with honey; and when they cannot be extracted by this simple means, they may sometimes be taken out with a small pair of forceps. In general, however, the most safe and expeditious practice for the removal of small insects, peas, beads, and other extraneous bodies, from the meatus auditorius, is to throw tepid water into the passage with a proper syringe, by which means they are forced out with the fluid. When the bead, or globular substance is small, (according to Mr. Buchanan) the best mode of extraction will be by means of the syringe, and injection of tepid water. For this purpose, the point of the syringe ought to be pressed gently against the edge of the meatus, so that it may occupy as little of the diameter of the tube as possible, and when the injection arrives at the membrana tympani, the regurgitation will force the bead, or other substance, outwards. If this be rather large, it may perhaps remain at the entrance of the meatus, whence it ought to be extracted by means of a pair of forceps. (See *Buchanan's Illustrations of Acoustic Surgery*, p. 40.)

[In this country, at least, the introduction of insects into the meatus is rare, and if the ova be deposited in the pus from a diseased tympanum, they probably die ere they become developed.]

In May, 1829, I was called to a child about two years and a half old, into one of whose ears a pebble, and into the other a French bean, had been pushed by another child, and remained there for ten months, causing complete deafness and extreme suffering. By throwing tepid water forcibly into the ear, I soon dislodged these foreign bodies, which lay close against the tympanum, entirely hidden by the swollen state of the lining of the ear, indurated wax, and dried discharge. With a bent probe their extraction was then readily effected. Several surgeons, previously consulted, had failed in their endeavours to remove the substances by other methods.

The presence of foreign bodies in the ear often occasions the most extraordinary symptoms, as we may see in the fourth observation of Fabricius Hildanus, Cent. 13. After four surgeons, who had been successively consulted, had in vain exerted all their industry to extract a bit of glass from the left ear of a young girl, the patient found herself abandoned to the most excruciating pain, which soon extended to all the side of the head, and which, after a considerable time, was followed by a paralysis of the left side, a dry cough, suppression of the menses, epileptic convulsions, and, at length, an atrophy of the left arm. Hildanus cured her, by extracting the piece of glass, which had remained

eight years in her ear, and had been the cause of all this disorder. Although the extraction must have been very difficult, it does not appear that Hildanus found it necessary to practice an incision behind the ear, as some authors have advised, and amongst them Duverney, who has quoted the foregoing case. We must agree with Leschevin, that such an incision does not seem likely to facilitate the object very materially; for, it must be on the outside of the extraneous substance, which is in the bony part of the canal. The incision enables us, in some measure, to avoid the obliquity of the passage, as Duverney has observed; but it is not such obliquity of the cartilaginous portion of the canal, that can be a great impediment; for, as it is flexible, it may easily be made straight, by drawing the external ear upward. Hence, Fabricius ab Aquapendente rejected this operation, first proposed by Paulus Ægineta; and it is justly disapproved of by Leschevin. (*Prix de l'Acad. de Chir.* t. ix. p. 147, édit. 12mo.)

Sabatier relates a case, in which a paper ball, which had been pushed into the meatus auditorius, made its way by ulceration into the cavity of the tympanum, where an abscess formed, which communicated with the interior of the cranium. (*Dict. des Sciences Méd.* t. vii. p. 8.)

[It is impossible too strongly to guard the practitioner against too great interference in attempts to remove these foreign bodies. It has frequently occurred to the writer of this article to witness the entire destruction of the tympanum in such endeavours. No attempt should be made unless the body is distinctly seen, or at all events prominently felt; the latter proof of its existence must, however, be received with very great caution. It has several times occurred to the writer to witness the long duration, in two or three instances for many years, of a foreign body in the meatus, which has unsuspectingly given rise to follicular and other abscesses, and occasional deafness; all which untoward effects subsided upon the removal of the offending material.]

6. *Meatus Auditorius obstructed with thickened or hardened Cerumen.*

The cerumen, secreted in the meatus auditorius by the sebaceous glands, frequently accumulates there in large quantities, and becoming harder and harder, at length acquires so great a degree of solidity as entirely to deprive the patient of the power of hearing. Galen has remarked, *è numero eorum quæ meatum obstruunt, sordes esse quæ in auribus colligi solent*. This species of deafness is one of those kinds which are the most frequent, and, at the same time, the most easy of cure. Formerly injections, either with simple olive oil, or oil of almonds, were recommended. The injection was retained by a piece of cotton, and when there was reason to believe that the matter was sufficiently softened, an attempt was made to extract it by means of a small scoop-like instrument. Various experiments were made by Haygrath, at Chester, in 1769, from which it appears that warm water is preferable to oil. The water dissolves the mucous matter which connects together the truly ceruminous particles, and which is the cause of their tenacity; other applications only succeeding by reason of the water which they contain.

The lodgment of hard pellets of wax, if neglected, may ultimately produce ulceration of the tym-

panum, and other serious mischief. Thus, in one case, Ribes and Chaussier found the handle of the malleus separated from its head, partly destroyed, and covered with the hardened cerumen that had made its way into the tympanum. (See *Dict. des Sciences Méd.* t. xxxviii. p. 30.)

"The symptoms (says Mr. Saunders) which are attached to the inspissation of the cerumen are pretty well known. The patient, besides his inability to hear, often complains of noises, particularly a clash or confused sound in mastication, and of heavy sounds, like the ponderous strokes of a hammer.

"The practitioner is led by the relation of such symptoms to suspect the existence of wax; but he may reduce it to a certainty by examination.

"Any means capable of removing the inspissated wax may be adopted; but syringing the meatus with warm water is the most speedy and effectual, and the only means necessary. As the organ is sound, the patient is instantaneously restored." (*Anatomy of the Human Ear, with a Treatise on its Diseases, by J. C. Saunders, 1806, p. 27, 28.*)

In order to throw an injection into the ear with effect, a syringe, capable of holding from four to six ounces, should be employed, and the fluid injected with a good deal of force, care being taken to let it enter in the natural direction, and not against one of the sides of the passage. The surgeon must also avoid pressing the pipe too deeply into the ear, so as to hurt the tympanum. As the fluid regurgitates with considerable rapidity, a small basin is to be held close up to the ear at the time of using the syringe, so as to catch the water, and hinder it from wetting the patient's clothes; for the surer prevention of which a napkin is also to be laid over the shoulder. In general it is necessary to throw the water into the ear six or seven times, or more, ere the pellets of wax are loosened, and entirely brought out; and sometimes, the injections will not completely succeed the first day on which they are employed. The evening before the syringe is to be used, a little warm water may be dropped into the ear.

[It not unusually happens that the patient, upon rising in the morning, finds himself deaf, not having been aware of a "hardness of hearing" some time previously; this new symptom is evidently occasioned by lying upon that side of the head, and the collection becoming moulded against the membrane of the tympanum. If any difficulty exist, or is expected, in the removal of the inspissated secretion, the ear had better be filled for a night or two with water, which is a better solvent than oil. In injecting, the water should be thrown along one side of the meatus, between the canal and the hard wax, and with force insufficient to excite pain.]

7. Imperfect Secretion of Wax.

When the wax is deficient in quantity, Mr. Buchanan recommends warmth and stimulant applications. He advises two drops of the following mixture to be introduced into the meatus auditorius, every night at bedtime:—*R.* Acid. Pyrolign. Spir. Ætheris Sulphur. Ol. Terebinth. āā M. One tablespoonful of the following medicine is also to be taken at the same time:—*R.* Tinct. Colchici 3iij. Aq. destillat. 3vj. M. If costiveness

prevail, the pilulæ rhei. comp. are to be given. (See *Buchanan's Acoustic Surgery, p. 60.*)

When the quality of the secretion requires improvement, the meatus is to be frequently washed out, and a little of the infusion of quassia with rhubarb and magnesia given once or twice a day. The warm bath is to be occasionally used at bedtime, and the following powder exhibited:—*R.* Hydrarg. chlor. gr. ij. Pulv. Ipecac. comp. ʒj. ft. Pulv. Horâ decubitûs sumend. In cases where the ear is preternaturally dry, and the cuticle of the meatus peels off, the ensuing injection is to be used every second or third day:—*R.* Acid. Pyrolign. 3ij. Aquæ destillatæ 3vi. ft. lotio; or the vapour of a mixture of equal parts of distilled water and pyroligneous acid introduced three times a week into the meatus with the aid of a glass retort. A little cotton should afterwards be put into the ear. (See *Buchanan's Acoustic Surgery, p. 62.*)

[This is a most rare cause of deafness, if it ever occurs as a primary disease; this deficient secretion is not at all infrequently a part of a general loss of power of the whole organ, usually sympathising with an anæsthenic auditory nerve. It also follows the various kinds of inflammation of the canal, particularly of the ceruminous follicles, and these especially may give rise to exfoliations of the cuticle. The remedy best suited to the latter condition is the ung. hydrar. nitr. melted and placed on the diseased part of the tube, and allowed to remain, or, being diluted, it may be frequently renewed; the various ointments of zinc, and of lead, are valuable applications.]

8. Discharges from the Meatus Auditorius.

Purulent discharges from the ear either come from the meatus auditorius externus itself, or they originate from suppuration in the tympanum, in consequence of blows on the head, abscesses after malignant fevers, the small-pox, or the venereal disease. [By far the most frequent cause of such discharges is scarlet fever, which occasions disease of the tympanum, as frequently as, perhaps more so than all the other exciting causes together; a circumstance to be expected from the tympanum being situated in the interval between the outer ear and the Eustachian tube, the exanthematous disease spreading along both canals.] In such cases the little bones of the ear are sometimes detached, and escape externally, and complete deafness is most frequently the consequence. However, in a few instances, total deafness does not follow even this kind of mischief, as I myself have witnessed on one or two occasions. [Deafness is not usually complete upon the loss of the ossicula, though the hearing is generally much affected; but even sometimes its diminution is hardly perceptible, particularly in the young, in whom the auditory nerve, and the general capability of appreciating lessened sounds, may be so much increased in power as to supply in a great measure the deficiency occasioned by the loss of the mechanical portion of the organ. It does not generally happen that the stapes comes away, and when such is the case, complete deafness usually results; it has, however, occurred to the editor of this article to be certainly assured of the escape of the stapes, with good hearing still remaining.] There is greater hope when the disorder is confined to the meatus; as judicious treatment may now avert the most serious consequences.

In Acrel's surgical cases, there is a case relative to the circumstance of which we are speaking. Suppuration took place in the meatus auditorius externus, in consequence of acute rheumatism, which was followed by vertigo, restlessness, and a violent headach. The matter discharged was yellowish, of an aqueous consistence, and acid smell. The meatus auditorius was filled with a spongy flesh. On introducing a probe, Acrel felt a piece of rough bone, which he immediately took hold of with a pair of forceps, and extracted. From the time when this was accomplished, the discharge diminished; and, with the aid of proper treatment, the patient became perfectly well.

The meatus auditorius, like all other parts of the body, is subject to inflammation. This is frequently produced by exposure to cold. It is hardly necessary to say, that generally topical bleeding and antiphlogistic means are indicated. The meatus auditorius should also be protected from the cold air, particularly in the winter season, by means of a piece of cotton.

Mr. Saunders observes, "When the means employed to reduce the inflammation have not succeeded, and matter has formed, it is generally evacuated, as far as I have observed, between the auricle and mastoid process, or into the meatus. If it has been evacuated into the meatus, the opening is most commonly small, and the spongy granulations, squeezed through a small aperture, assume the appearance of a polypus. Sometimes the small aperture, by which the matter is evacuated, is in this manner even closed, and the patient suffers the inconvenience of frequent returns of pain from the retention of the discharge. When the parts have fallen into this state, it will be expedient to hasten the cure by making an incision into the sinus, between the auricle and mastoid process."

"It occasionally happens, that the bone itself dies in consequence of the sinus being neglected, or the original extent of the suppuration. The exfoliating parts are the meatus externus of the os temporis, or the external lamina of the mastoid process." (P. 24, 25.)

[A follicular abscess, or an abscess occurring in one or more of the ceruminous follicles, is a very fruitful source of such a discharge; it is often attended with extreme suffering from the non-yielding character of the surrounding parietes; and from the distension occupying the canal, complete deafness results, to be relieved only upon the subsidence of the tumefaction. These abscesses frequently require to be opened, and are to be treated with warmth and moisture in the ordinary manner.]

In some examples of purulent discharge from the ear, and particularly in scrofulous patients, Mr. Buchanan employs alterative medicines, as calomel, the tincture of iodine, and the compound rhubarb pills of the *Edin. Pharmacopœia*. He also sometimes has recourse to the pyroligneous injection. (See *Illustrations of Acoustic Surgery*, p. 93, &c.) Some additional cases in favour of the efficacy of iodine, in certain forms of deafness, may be found in Dr. Manson's work. (See *Medical Researches on the Effects of Iodine*, 8vo. London, 1825.)

9. Excrescences in the Meatus Auditorius.

Though the membrane lining the meatus auditorius is very delicate, it is not the less liable to be-

come thickened, and to form polypous excrescences. As such tumors are ordinarily firmer in their texture than polypi of the nose, they are sometimes not so easily extracted with forceps. When they are situated near the external orifice, and admit of being taken hold of with a small pair of forceps, or a hook, and drawn outwards, they may easily be cut away. Sometimes the excrescences, instead of being adherent by a narrow neck, have a broad base, which occupies a considerable extent of the passage. In such cases, the use of escharotics has been proposed; but, they cannot be used without risk of injuring the tympanum. Mr. Buchanan prefers the practice of removing polypi of the meatus with forceps, and afterwards touching the part from which they grew with the ung. hydrarg. nitrat. or tinct. ferri muriatis. (*Acoustic Surg.* p. 74.) He also recommends washing out the passage every day with the injection, R. Acid. Pyrolign. ʒij. Aq. destillatæ ʒvj. ft. lotio. I lately attended a lady, who had a round smooth tumor growing from the membrana tympani, to which it was attached by means of a long pedicle. It nearly filled the meatus, and was attended with a discharge. With the assistance of Mr. Morton, of University College, I cut through its pedicle, removed it, and then applied the nitrate of silver. But, in a few weeks, it grew again, and it was once more removed with the same result. I next intended to twist it off; but it was attacked with inflammation, and sloughed away. I do not at present know whether it is growing again.

10. Herpes of the Meatus Auditorius.

An herpetic ulcerous eruption sometimes affects the meatus auditorius and auricle, producing considerable thickening of the skin, and so great an obstruction of the passage, that a good deal of deafness is the consequence. Mr. Saunders remarks, that, in this case, "the ichor, which exudes from the pores of the ulcerated surface, inspissates in the meatus, and not only obstructs the entrance of sound, but is accompanied with a great degree of fetor. This disease is not infrequent. I have never seen it resist the effect of alterative medicines," the use of injections containing the bichloride of mercury, and the application of the unguentum hydrargyri nitratis. Mr. Saunders exhibited calomel as the alterative, and in one instance, employed a solution of the nitrate of silver as an injection. (P. 25, 26.) When the disease is obstinate, a seton should be made on the nape of the neck, or a blister be applied behind the ear. The tincture of iodine should also be tried.

[Extreme cleanliness is of the utmost importance in these and similar affections; in addition to which astringent lotions appear to be the most available, as the solutions of lead, of alum, of zinc, &c. A very useful form is liq. plumb. diacet. ʒss., acidi acetici diluti ʒss., aquæ ʒvij., to be dropped into the ear two or three times a day, or syringed in night and morning, as the urgency of the case may require.]

11. Affections of the Tympanum.

The ear is sometimes affected with a puriform ichorous discharge, attended with a loss of hearing, proportionate to the degree of disorganisation which the tympanum has sustained. Frequently, on blowing the nose, air is expelled at the meatus

auditorius externus; and, when this is the case, it is evident that the discharge is connected with an injury, or destruction of the membrana tympani. However, when the Eustachian tube is obstructed with mucus, or matter, or when it is rendered impervious, and permanently closed by inflammation, the membrana tympani may not be perfect, and yet, it is clear, no air can in this state be forced out of the external ear in the above manner. An examination with a blunt probe, or with the eye, while the rays of the sun fall into the passage, should therefore not be omitted. If the membrane have any aperture in it, the probe will pass into the cavity of the tympanum, and the surgeon feel that his instrument is in contact with the ossicula, or internal wall of the tympanum.

In this manner, the affection may be discriminated from an herpetic ulceration of the meatus auditorius externus. The causes are various: In scarlatina maligna, the membrana tympani occasionally inflames and sloughs; the ossicula are all or in part discharged, and, if the patient live, he often continues quite deaf. An earach, in other words, acute inflammation of the tympanum, is the most common occasion of suppuration in this cavity, in which, and the cells of the mastoid process, a good deal of pus collects. At length the membrana tympani ulcerates, and a large quantity of matter is discharged; but, as the secretion of pus still goes on, the discharge continues to ooze out of the external ear.

[In cases where the membrana tympani is absent, the use of the artificial membrana tympani has been suggested by Mr. Toynbee—cotton wool by Mr. Yearsley.]

Instead of stimulating applications, inflammation of the tympanum demands the rigorous employment of antiphlogistic means. Unfortunately, it is a too common practice, in this case, to have recourse to acrid spirituous remedies. Above all things, the repeated application of leeches to the skin behind the external ear, and over the mastoid process, should never be neglected. As soon as the inflammation ceases, the degree of deafness, occasioned by it, will also disappear. This, however, does not always happen.

When an abscess is situated in the cavity of the tympanum, Mr. Saunders thinks that the membrana tympani should not be allowed to burst by ulceration, but be opened by a small puncture. (P. 31.) However, unless there were the strongest ground for believing, that the Eustachian tube were impervious, this advice, I think, ought not to be followed, more especially as the symptoms are generally too vague to afford any degree of certainty in the diagnosis.

Sometimes the disease, of which we are treating, is more insidious in its attack: slight paroxysms of pain occur, and are relieved by slight discharges. The case goes on in this way, until, at last, a continual discharge of matter from the ear takes place. The disorder in its tendency is destructive to the faculty of hearing, and it rarely stops until it has so much disorganised the tympanum and its contents, as to occasion total deafness. Hence, Mr. Saunders insists upon the propriety of making attempts to arrest its progress,—attempts which are free from danger; and he censures the foolish fear of interfering with the complaint, founded on the apprehension, that bad constitutional effects may originate from stopping the discharge.

If the case be neglected, the tympanum is very likely to become carious; before which change, the disease was considered by Mr. Saunders, to be mostly curable.

Mr. Saunders divides the complaint into three stages:—1. A simple puriform discharge. 2. A puriform discharge complicated with fungi and polypi. 3. A puriform discharge with caries of the tympanum. As the disease is local, direct applications to the parts affected are chiefly entitled to confidence. Blisters and setons may also be advantageously employed. Mr. Saunderson's practice consisted in administering laxative medicines and fomenting the ear, while inflammatory symptoms lasted, and afterwards injecting a solution of the sulphate of zinc, or acetate of lead.

In the second stage, when there were fungi, he removed or destroyed them with forceps, afterwards touched their roots with the nitrate of silver, or injected a solution of alum, sulphate of zinc, or nitrate of silver.

Writers describe a relaxed state of the membrana tympani, as a cause of deafness. If, says a late author, after a discharge from the meatus auditorius externus, or cavity of the tympanum, or a dropsy of the latter cavity, the hearing remains hard, there is reason to suspect, that the infirmity may depend upon relaxation of the membrane of the tympanum, or paralysis of the internal muscle of the malleus. This suspicion will be strengthened, if the deafness should increase in damp, and lessen in dry, weather; and particularly, if it be found, that the hearing is benefited by introducing into the ear dry warm tonic applications, such as the smoke of burning juniper-berries, or other astringent vegetable substances. The decoction of bark, used as an injection, is also said to have done good.

The relaxation of the tympanum, alleged to proceed from a rupture of the muscle of the malleus, is deemed incurable; but it is not so with the case, which depends upon paralysis of this muscle. Here tonic injections into the tympanum, through the Eustachian tube, are recommended. (*Dict. des Sciences Méd.* t. xxxviii. p. 50.) Electricity, stimulating liniments, gargles, a blister, or the external use of strychnia, might also be tried.

Imperfect hearing is supposed sometimes to arise from preternatural tension of the membrane of the tympanum, indicated by the patient hearing better in wet than dry weather, and by his hearing what is spoken in a low tone, near his ear, better than anything said in a loud manner. The opinions delivered by writers on the causes of this affection are only uncertain conjectures. The local treatment recommended consists in injecting into the meatus auditorius emollient decoctions, or warm milk, or introducing into the passage a dossil of soft cotton, dipped in oil of sweet almonds. Nothing certain is known respecting the proper constitutional treatment, as must be clear from our ignorance of the causes of this form of disease of the ear.

Hardness of hearing appears sometimes to be caused by a chronic thickening of the membrane of the tympanum; and it is alleged, that there are cases of this description, which proceed from syphilis, and require mercury. An issue in the arm nearest the affected ear, the tincture of iodine, and emollient and slightly stimulant injections, are likewise commended. When the tympanum

was so considerably thickened, that there was no chance of restoring it to a healthy state, Portal questioned whether it might not be advisable to make a small opening in it? (*Précis de Chir. Pratique*, t. ii. p. 430.) This operation, which is said to have been first suggested by Cheselden, will be considered in the ensuing section.

Morgagni found the cavity of the tympanum intersected by numerous membranes, which impeded the movements of the ossicula. (*Epist. an. vi. § 4.*)

Meckel does not mention any example of a deficiency of all the ossicula. (*Handb. des Pathol. Anat. b. i. p. 402.*) Mersanni, however, found the incus wanting. (*Bonet Sepulch. t. i. sect. 19, obs. 4, § 1.*) Caldani, the malleus and incus. (*Epist. ad Haller, t. vi. p. 142.*) The latter case was unattended with any bad effect on the hearing; the first with deafness. In a deaf child, three years of age, Bailly found the ossicula of only $\frac{1}{3}$ their proper size. (*Bonet Sepulch. t. i. sect. 19, obs. 4, § 3.*) In an example, where the fenestra rotunda was obstructed, Cotunnus found the ossicula twice as large as natural. (*De Labyrinthi Auris contentis, § 72, and Meckel's Handb. des. Pathol. Anat. b. i. p. 402.*) A case, in which all the ossicula were wanting, is on record. (See *Dict. des Sciences Méd. t. xxxviii. p. 114.*)

[Of the causes of deafness alluded to in this section—"affections of the tympanum"—the most common are: 1st. *Myringitis*, or inflammation of the membrana tympani, which most frequently commences in a subacute form, affording but little other indication of the disease beyond the resulting deafness, until it be examined in a good light. It may commence in the acute or chronic condition, then exhibiting the appropriate symptoms of severity or slowness; in the former case the cardinal signs of inflammation are very marked and prominent, yet unaccompanied by deafness until a change in the organisation of the membrane is effected beyond the mere increased vascularity. In the latter state effusion of fibrine takes place between the layers of the membrane, thickening its structure, and giving rise to a very marked deafness. Acute myringitis, when uncomplicated, most frequently subsides upon appropriate treatment; but it may terminate in ulceration, either through the membrane, or confined to the surface, or an aphthous appearance of the cuticular coverings may result: granulations from these ulcerated surfaces may occur, producing the vegetations to which allusions have already been made.

2nd. *Tympanitis*, or inflammation of the mucous membrane lining the cavity of the tympanum. This affection may be simply of the catarrhal character, producing an accumulation of mucus, and of course corresponding deafness, resulting from the impossibility of the vibrations of the membrane or the oscillations of the bones being maintained; a condition which generally subsides as the cause passes away, the mucus either escaping through the Eustachian tube or becoming absorbed. The tympanitis often extends to the submucous tissue, to the proper textures of the membrana tympani, occasioning myringo tympanitis, and terminating in thickening of the whole structures, or in the formation of bands of fibrine ankylosing the ossicles together and to the fenestra ovalis, and thus not infrequently producing permanent deafness. These circumstances ought to direct the surgeon's careful attention to the treat-

ment of such cases in their early and incipient form. Acute tympanitis also terminates in suppuration of the cavity of the tympanum, which happily usually extends through the membrane, and thus the pus finds its customary discharge; it sometimes, more happily still, finds an escape through the Eustachian tube; which, however, in these severe cases is generally nearly closed towards the tympanic cavity: suppuration also extends backwards into the mastoid process, diseasing those cells. Disease of these cells not at all infrequently extends outwards through the bony parietes, forming external abscess, which is most constantly seated between the periosteum and the bone. Severe cases of tympanitis will ulcerate the parietes of the tympanum, and thus extend the disease through the walls to the dura mater and to the brain; it most frequently finds its way through the superior surface, but the inflammation of the bone is often traceable through the posterior as well as the anterior wall. This most severe form of tympanitis is constantly the result of malignant scarlet fever, as has been already observed. Further, it not infrequently happens that suppurations of the tympanum extend to the aqueduct of Fallopius, paralysing the portio dura, either by directly implicating that nerve in the disease, or by simple pressure of the pus upon its structure. The treatment in these various forms of inflammation must be for the most part strictly antiphlogistic, and conducted upon the ordinary principles of surgery. Catheterism of the Eustachian tube is often a most valuable adjunct in accumulations of mucus in the cavity of the tympanum.]

12. Obstruction of the Eustachian Tube.

This is often the cause of a considerable degree of deafness, because it is necessary for perfect hearing, that air should be conveyed from the mouth through this passage into the cavity of the tympanum, which now can no longer happen.

A degree of deafness generally attends a severe cold, which is accounted for by the Eustachian tube being obstructed with thickened mucus. Mr. Saunders tells us, that the obstruction most frequently arises from syphilitic ulcers in the throat, or sloughing in the cynanche maligna. The deafness comes on when such sores are healed, that is, when the obstruction is complete. The descent of a nasal polypus into the pharynx, and enlarged tonsils, have also been known to close the tube. (P. 42.)

When the Eustachian tube is obstructed, the patient cannot feel the membrana tympani crackle, as it were, in his ear, on blowing forcibly with his nose and mouth stopped. A history of previous ulceration, or disease, of the throat will sometimes facilitate the diagnosis.

When the Eustachian tube is obstructed with mucus, it has been proposed to employ injections, which are to be thrown, by means of a syringe and catheter, into the guttural orifice of that canal. This operation will be presently described. [True stricture of the Eustachian tube is of rare occurrence, though it has been frequently described.]

Sir A. Cooper had noticed, that hearing was only impaired, not lost, when suppuration in the tympanum had injured, and even destroyed the membrana tympani, and that the degree of deafness by no means equalled what resulted from an obstruction of the Eustachian tube. Hence, when the tube was permanently obliterated, he conceived,

that a small puncture of the membrana tympani might be the means of enabling the patient to hear. This gentleman reports four cases, in which the experiment was made with success.

The operation consists in introducing an instrument, resembling a hydrocele trocar, but curved, into the meatus auditorius externus, and pushing it through the anterior and inferior part of the membrana tympani; a place rendered most eligible, on account of the situation of the chorda tympani and manubrium of the malleus, parts which should be left uninjured. The instrument must not be introduced far, lest it wound the vascular lining of the tympanum, and cause a temporary continuance of the deafness, by an effusion of blood. When the puncture is made, in proper cases, and in a judicious manner, hearing is immediately restored. A small hole in the membrana tympani now conveys the air into the cavity of the tympanum, answering the same purpose as the Eustachian tube.

The surgeon will be able to operate with more ease, if he take care to lessen the curvature of the meatus auditorius by drawing upward the external ear.

There is some chance of a relapse in consequence of the opening closing up. This consideration led Richerand to propose making the aperture with caustic, so as to destroy a part of the membrane. (*Nosogr. Chir.* t. ii. p. 132, éd. 2.) This suggestion is not likely to be adopted on account of the inconveniences of applying caustic within the ear. Mr. Saunders is an advocate for making the opening large. However, perhaps the best method of doing the operation both effectually and safely is that lately described by Mr. Buchanan of Hull, the chief peculiarity of whose mode consists in *drilling* the perforation. The quadrangular point of his perforator cuts the fibres of the membrana tympani across; they retract; the wound assumes an oval shape; and there is less danger of its closure again, than after the common plan of making a single puncture. "A room (says Mr. Buchanan) with a window fronting the south, should be chosen for the place of the operation; and the patient placed on a low seat, so that the rays of the sun may fall into the meatus. The manubrium, or handle of the malleus will then be distinctly seen, pointing downwards and inwards; occupying the superior half of the membrana tympani. The surgeon being seated on a high chair, should lay his left hand on the head of the patient, and, with the right, take hold of the instrument in the same manner as he would a pen when writing: he should then cautiously and steadily enter the point of the perforator into the membrana tympani, about half-way between the centre and its lower edge, and, with the thumb and index finger, give the instrument half a turn one way, and then half a turn the other, and in this manner gently push the point about a line through the membrane." (See *Engraved Representation of the Anatomy of the Ear*, p. 33.) Mr. Saunders, by puncturing the tympanum, instantaneously restored the hearing of one patient, who had been deaf thirty years in consequence of the destruction of a part of his palate by syphilis. (P. 45.) In an instance where a young man had been deaf for eight years, apparently from obstruction of the Eustachian tube by swellings and disease about the throat, Paroisse also restored the

hearing directly, by perforating the anterior and inferior part of the tympanum. (*Opusculs de Chir.* p. 309, 8vo. Paris, 1806.) The practice has also been successfully adopted by Michaelis in one case, and Hunold has tried it in a vast number of examples, two-thirds of which succeeded. (*Dict. des Sciences Méd.* t. 38, p. 63.) Sir A. Cooper's cases are in the *Phil. Trans.* for 1802.

Puncturing the membrana tympani has been attended with some degree of success in France, where it has been tried by Itard, Celliez, and Maunoir, &c. It is not to be dissembled, however, that it is liable to failure. Dubois performed the operation in four instances without success. (*Richerand, Nosogr. Chir.* t. ii. p. 132.)

In most cases the patients benefited are said to have experienced pain just after the trocar was withdrawn. The organ, not being accustomed to sound, had become so extremely sensible, that it could not bear the gentlest impression of the sonorous vibrations; and the patient's first request, after the perforations had been made, was, that persons near him, might speak softly. This excessive tenderness of the sense gradually subsides.

The two principal objections made to the foregoing practice, are the risk of injuring that part of the tympanum which is connected with the malleus, and the tendency of the puncture to heal up again. (See *Dict. des Sciences Méd.* t. xxxviii. p. 57; *Maunoir in Journ. de Méd.* t. xiii.; *Sabatier, Traité d'Anatomie*, t. ii. p. 186.) The author of the article Oreille in the latter dictionary, who cannot, however, be deemed at all partial to the operation, delivers the following judgment concerning it:—1. It is the only operation, which is likely to answer, where the tympanum is cartilaginous or ossified, and the rest of the organ is sound. 2. It will be attended with some success, where the Eustachian tube is closed, and this defect cannot be otherwise removed. 3. It will be useless where the cavity of the tympanum is filled with matter, which is too thick to escape through the puncture. 4. When deafness depends on paralysis of the auditory nerve. 5. When the infirmity arises from inflammation of the ear or nervous irritation. 6. Or from fevers, the Eustachian tube being pervious.

[The operation of puncturing the membrana tympani is not now often performed; and most probably in consequence of the facility with which the Eustachian tube can be catheterised, and the obstructions, where they exist, removed. But more particularly in consequence of the general failure of the operation.]

Wathen, Boyer, Itard, Buchanan, and the latest surgeons, who have considered the operation of injecting fluids into the Eustachian tube, agree, that it is more easily performed by passing the tube through one of the nostrils, than the mouth. The patient being seated on rather a low chair, with his head supported upon the breast of an assistant, standing behind him, the surgeon takes a probe, which is bent towards its end to an angle of about 135°, and he introduces it, with the end turned downwards, along the floor of the nostril, and, when it has reached the pharynx, a circumstance denoted by its descent behind the soft palate, a rotatory movement outwards to the extent of a quarter of a circle is given to it, and the handle is inclined downwards and inwards. The instrument's becoming fixed denotes its entrance into the

Eustachian tube. (See *Ph. F. Blandin* in *Dict. de Méd. et de Chir. Pratiques*, t. xii. p. 280.) Wathen's instruments are described in the *Phil. Trans.* 1794; those of Boyer in *Traité des Mal. Chir.* t. vi. p. 391; those of M. Itard, which deserve particular notice, in his *Traité des Mal. de l'Oreille*; and those of another modern advocate for this operation, in *Dict. des Sciences Méd.* t. xxxviii. p. 108. The latter author, after stating how his tubes, which are four French inches in length, and shaped somewhat like an italic *S*, are introduced, enumerates the following as the advantages derived from their employment. 1. Fluid applications may be conveyed into the Eustachian tube, the cavity of the tympanum, and the mastoid cells, and deeply seated obstinate ulcerations within these parts cured. 2. The same parts can be cleared from any mucus by which they are obstructed. 3. Blood extravasated within the tympanum, from blows on the head, can be washed out. 4. Chalky substances, which sometimes form in the tympanum, may be brought out in the same manner. 5. Through the tube a stilet can be passed into the Eustachian tube, so as to perforate a congenital septum, or any cicatrix, obstructing the entrance of that passage. 6. When the sensibility of the auditory nerve is dull, the effect of fluids, thrown into the tympanum, can be tried. (See also *T. Buchanan's Engraved Representation of the Anatomy of the Human Ear*, p. 28, fol. Hull, 1823.)

[Mr. Toynbee, in his recent treatise on the Diseases of the Ear, has shown that the Eustachian tube is shut except during the momentary act of swallowing, during which act the air can be heard to enter the tympanic cavity by means of the otoscope, if the mouth and nose are closed. The Eustachian catheter as a means of diagnosis is consequently not needed.]

13. Of perforating the Mastoid Process.

Of all the cases of deafness for which Arnemann and others have recommended this operation, that attended with an abscess and caries of this process is the only one, in which the practice is now at all sanctioned. An instance is related by Jasser, in which the carious surface of the right mastoid process was exposed by an incision, and an opening detected with a probe. An injection was thrown into the aperture with a syringe, when, to the astonishment of Jasser and his patient, the fluid gushed out of the right nostril. The plan was repeated for a few days, and at the end of three weeks, the part was healed, and the hearing greatly improved. This success induced Jasser to make a perforation in the left mastoid process, the ear on that side being deaf, and to employ the injection, which was also discharged from the left nostril. The hearing, however, was not so completely restored in this as it had been in the right ear; but the wound healed up without any exfoliations. (*Journ. de Méd. Fév.* 1793.) The idea of perforating the mastoid process was suggested long before the time of Jasser. Riolan, in various parts of his works, mentions the propriety of making a small perforation in several cases of deafness, and tinnitus aurium, attended with obstruction of the Eustachian tube. Rolfincius also advised a similar opening to be made in the mastoid process with a trocar, in cases of dropsy of the cavity of the tympanum and of the mastoid

cells. Jasser, however, was the first who actually made the experiment, and his example was followed by Hagstroem, whose attempt did not succeed, the completion of the operation having been interrupted by profuse hæmorrhage, and no benefit done to the hearing. The injections also appear to have caused, in this instance, alarming symptoms, violent pains in the head, loss of vision, sense of suffocation, and syncope. The fluid entered the mastoid cells, without any of it issuing, either by the nostrils or mouth. (*Op. cit.*)

The operation was successfully tried by Löffler. The injection did not pass into the mouth, yet the hearing was restored, though it was lost again when the wound closed. Hence a new opening was made, and kept from healing by means of a piece of catgut. The patient was afterwards able to hear when his mouth was open.

The perforation of the mastoid process was not approved of by Morgagni; indeed, it must often fail, as both Morgagni and Hagstroem have observed, on account of complete bony partitions preventing all communications between the mastoid cells; and sometimes the mastoid process, instead of being cellular, is perfectly solid, an instance of which is recorded by A. Murray. In children, the mastoid cells are but imperfectly developed, and the operation may bring on caries, necrosis, erysipelas, &c. (See *Blandin* in *Dict. des Méd. et de Chir. Pratiques*, t. xii. p. 281.)

[The performance of this operation is now wisely never had recourse to except in well-recognised disease of the mastoid cells, and generally to afford an escape for the matter contained in the cells, or for the removal of diseased bone.]

14. Diseases of the Labyrinth.

These are much more diversified than might, at first, be supposed, and, if we admit the two doubtful cases, said to depend upon the state of the lymph of Cotunnus, there are not less than seven different species of disease affecting the labyrinth:—1. Disease of the fenestra ovalis, and fenestra rotunda, as ulceration, thickening, &c. 2. Malformation of these apertures. 3. Malformation of the labyrinth. 4. Inflammation of the nervous membrane, which lines its cavities. 5. Alteration of the liquor of Cotunnus. 6. Deficiency of the same fluid. 7. Affections of the nerve of hearing.

No doubt deafness (and that kind of it which so frequently foils the most skilful men) often arises from an insensible state of the portio mollis of the auditory nerve, or of the surfaces on which its filaments are spread. This affection is analogous to amaurosis, in which, though every part of the eye may seem to possess its natural structure, sight is lost, because the rays of light only strike against a paralytic, or insensible retina. Mr. Saunders dissected the ears of two deaf patients with the greatest care, but could not discover the least deviation from the natural structure. In the commencement of deafness from a paralytic affection of the auditory nerve, Sir A. Cooper remarked, that the secretion of cerumen was diminished, and, when the deafness became worse, was totally suppressed. And another particular symptom of paralysis of the auditory nerve, pointed out by the same author, is the patient's inability to hear the sound of a watch placed between the incisor teeth.

With respect to the causes of a paralytic affec-

tion of the auditory nerve, they are mostly buried in great obscurity, and some of them probably depend upon congenital imperfection of the nerve, or brain itself. It seems, however, that a part of the causes to which we allude, act mechanically, as an extravasation of blood, a steatoma, or an exostosis; while others operate on the ear by sympathy, as is the case when deafness is produced by the presence of worms in the bowels.

Mr. Saunders remarks, that all the diseases of the internal ear may be denominated nervous deafness; the term, in this sense, embracing every disease, the seat of which is in the nerve, or parts containing the nerve. Nervous deafness is attended with various complaints in different cases, noises in the head of sundry kinds, the murmuring of water, the hissing of a boiling kettle, rustling of leaves, blowing of wind, &c. Other patients speak of a beating noise corresponding with the pulse, and increased by bodily exertion, in the same degree as the action of the heart. (*Saunders*, p. 47.) [This is a circumstance of very common occurrence, and is evidently produced by the pulsations of the internal carotid artery being heard by the excited or erethistic auditory nerve.]

According to this author, there is a syphilitic species of nervous deafness, attended with a sensation of some of the above peculiar noises; and one case is related, in which the hearing was completely restored, in five weeks, by a mercurial course.

Mr. Saunders relieved several cases of nervous deafness by confining patients to low diet, giving them calomel freely, repeated doses of sulphate of soda, or magnesia, sometimes twice, sometimes thrice, a week, or according to circumstances, and applying blisters behind the ears at intervals of a week. The plan requires perseverance.

[Many cases of ankylosis of the stapes described by Mr. Toynbee have doubtless been confounded with those of nervous deafness.]

Electricity has been highly recommended for the cure of nervous deafness, though the prospect of benefit from it must entirely depend upon the nature of the cause of the infirmity. It is allowed to be sometimes useful in cases of incomplete paralysis of the auditory nerve; but it cannot be of any service where the Eustachian tube, the cavity of the tympanum, or the mastoid cells, are obstructed. It is set down as hurtful, when the patients are very irritable, and subject to vertigo, bleeding from the nose, great determination of blood to the head, &c. (*Dict. des Sciences Méd.* t. xxxviii. p. 124.) The evidence in favour of the efficacy of galvanism, is still more scanty and questionable. [Electricity, in the modified forms of electro-galvanism, magnetico-galvanism has been administered, and invariably without success when applied in the usual manner upon the surface of the neighbourhood of the ear. The writer has been in the habit of administering it through the Eustachian tube, using the catheter as one conductor, and applying the other in the external auditory canal, thus allowing but little more than the tympanum to intervene between the two conductors: and in a small minority of cases the practice appears to have been attended with advantage. Kramer has introduced the vapour of acetic ether in such cases, and he states with wonderful success, though in the later editions of his work he appears to have urged the practice less

forcibly; many of his supposed instances of erethistic or excited auditory nerve were most probably cases of myringo-tympanitis, or chronic affections of the nervous membrane itself. The writer not infrequently injects a minute quantity of acetic ether, very largely diluted, into the cavity of the tympanum, with, however, doubtful benefit.]

Whether, in certain cases of deafness from torpor of the auditory nerve, the introduction of tonic injections into the cavity of the tympanum, through the Eustachian tube, will answer in the manner stated by a late writer, future experience must determine. (*Dict. des Sciences Méd.* t. xxxviii. p. 120, 121.) The tincture of iodine, blisters, mercury, and the external use of strychnia, are means often deserving a fair trial.

This article, I think, may be usefully concluded with a few general, but sensible, observations on the various kinds of deafness, made by a modern writer. According to Professor Rosenthal, all the disorders of the sense of hearing may be comprised under three principal forms.

1. Deafness (*Surditas, Cophosis*), in which the faculty of hearing articulated sounds is completely annihilated.

2. Hardness of hearing (*Dysœcia*), in which this faculty is so diminished, that articulated sounds cannot be heard, without the assistance of a particular apparatus.

3. Alteration, or diminution of hearing (*Paracusis*), in which the faculty of hearing articulated sounds, in the natural way, is imperfect for want of precision.

1. *Deafness*, Rosenthal distinguishes into two degrees; the first of which is marked by an absolute impossibility of hearing at all; the second, by a power of still distinguishing certain sounds, as whistling, the vowels, &c. The first is usually congenital, and a cause of dumbness.

The discrimination of these two degrees, Rosenthal considers of great importance in practice, and especially in institutions for the deaf and dumb; because the exceedingly fine sense of touch, with which dumb persons are sometimes gifted, is apt to be mistaken for the faculty of hearing. This fact is illustrated by some interesting experiments made by Pfingsten on deaf and dumb persons. (*Vieljährige Erfahrung über die Geheerfehler der Taubstummen*, Kiel, 1802, p. 32.) A deaf and dumb girl, who was at needlework in a room near the house door, regularly gave notice whenever it was opened or shut. As the door was furnished with a little bell, which rang loud enough whenever the door moved to be plainly heard in the neighbouring room, and with the exception of this noise, no other impulse nor shock could be distinguished, Pfingsten was surprised at the circumstance. Desirous of ascertaining how the girl really knew about the movements of the door, he caused the bell to be rung with great force without the door being opened: the child was perfectly unconscious of the noise. The bell was afterwards kept still, while a person opened and shut the door so softly, that Pfingsten himself could not hear it; yet, the child instantly gave warning that somebody had entered. The inference was, that the chair, on which she sat, communicated to her legs and back a certain impulse, which made her conscious of the motion of the door.

The dissection of the ears of deaf and dumb persons has brought to light some facts, explanatory of

the cause of the loss of hearing. Amongst other things, it appears, that complete deafness, whether congenital or acquired, more frequently depends upon morbid alterations of the soft parts, than upon any irregularity in the formation of the bones. Thus, in the body of a person, who had been deaf and dumb while living, Hoffmann found the auditory nerve diminished in size, while every other part of the organ was perfectly natural. Arnemann found the nerve harder than common. Dr. Haighton met with an instance, in which the vestibule was filled with a caseous substance. (*A Case of original Deafness, in Mem. of the Med. Society, vol. iii. p. 1—15.*) Duverney and Sandifort found the auditory nerve strongly compressed by a steatoma. In one case, Itard found every part of the ear apparently so natural, that the deafness could not be ascribed to paralysis of the nerve. In another, the infirmity depended upon obstruction of the passages. In a third, the cavity of the tympanum, and the vestibule, contained small portions of calcareous matter. He has also seen the tympanum filled with a thick yellow lymph, or a thin fluid enclosed in membranous cells. In the dissection of the body of a deaf and dumb person, Rosenthal noticed amongst other remarkable circumstances, a greater hardness of the auditory, than of the facial nerve, and preternatural firmness of the medulla oblongata; thickening of the membrane of the tympanum; the bony roof of the cavity of the tympanum not thicker than paper; and just over the junction of the malleus with the incus, the bony substance was so absorbed, that an appearance like that of membrane alone remained. The mastoid cells, cavity of the tympanum, and the Eustachian tubes, contained a limpid yellow fluid. In the tympanum, the periosteum was thickened, forming small cells around the ossicula, which were of their natural structure. Nothing particular was remarked in the labyrinth.

In a small proportion of instances, the above degree of deafness has been traced to anomaly in the structure of the solid parts. Thus, Mundini found the cochlea composed of only one circle and a half. (*Opusc. Acad. Bonon. 1791, t. vii. p. 422.*) Valsalva found the stapes adherent to the fenestra ovalis (*De Aure Humanâ, cap. 11*); and Reimarus relates a case in which the ossicula were entirely wanting. (*Kunstribe der Thiere, p. 57.*)

Mr. Edward Cock has examined the temporal bones of five children, who died of strumous diseases of the thoracic and abdominal viscera, in the Asylum for the Deaf and Dumb. In three instances, one or both ears were the seat of scrofulous ulceration, affecting the tympanum and meatus externus, with partial destruction of the membrana tympani. In one case, the cavity of the tympanum, together with the mastoid cells, was completely filled with the thick cheesy deposit of scrofula, whilst a similar affection pervaded the whole cancellated structure of the petrous bone. The connexions of the ossicula were destroyed, but the bones themselves remained entire. In all the cases examined by Mr. Cock, the petrous portions of the temporal bones exhibited more than the usual varieties of size and shape. In some, the bone was so deficient in particular spots, as barely to cover the internal cavities, whilst, in others, there was a preternatural osseous development. In one instance, the petrous bone of a child, twelve years old, exceeded in size, hardness, and compactness of

structure, that of an adult. One malformation, discovered in two cases, consisted in a partial deficiency of two of the semi-circular canals. Their extremities opening into the vestibule, were perfect, but the central portions were impervious, or rather did not exist at all. In one case the scala tympani was terminated at its larger extremity by a bony septum, which separated it from the tympanum, and occupied the situation of the membrane of the fenestra rotunda. With the exception of these malformations, and the scrofulous affections of the tympanum, already mentioned, which were probably of recent occurrence, no deviation from the healthy state could be discovered in either of the five subjects examined. The Eustachian tubes were pervious; the bones, muscles, and membranes entire and natural; the labyrinths were filled with their transparent fluid; and the auditory nerve presented no peculiarity. The chorda tympani existed in each of the cases; but the integrity of all its little filaments, passing into the tympanum, and requiring a microscope for their dissection, could not be vouched for. (*E. Cock in Med. Chir. Trans. vol. xix. p. 152.*) In a case, dissected by Mr. Dalrymple, the aqueduct of the vestibule was large enough to admit a small probe; and, in a later examination of the ear of a child, who died in the Asylum for the Deaf and Dumb, Mr. Cock could find no vestige of the fenestra rotunda on either side, the usual situation of the membrane being occupied by solid bone. The temporal bones were exceedingly large, though soft and spongy. The cavities were extraordinarily capacious, and the Eustachian tubes three or four times larger than common. On one side, the aqueduct of the vestibule readily allowed the passage of a large bristle; but, on the other side, the canal could not be traced through the bone, although its two extremities were more than usually expanded. In one tympanum, suppuration had taken place. (*E. Cock, ib.*) See a table in Mr. Toynbee's work on the Diseases of the Ear, and of the morbid condition of the ears of the Deaf and Dumb, as shown by dissection.

In the first degree of deafness above described, which, when congenital, must excite suspicion of serious malformation of the organ, and abolition of the nervous influence, and when acquired, indicates a complete injury of the functions of the nerve, the prognosis, as Rosenthal observes, must be unfavourable. Nor can it be otherwise in the second *congenital* degree of the disease, though only a partial imperfection of the organ and nerve can here be supposed. On the other hand, when the latter degree is *acquired*, there is more prospect of relief, because merely a partial alteration in the soft parts is to be suspected.

2. *Hardness of hearing.* Rosenthal also distinguishes several degrees of, what is termed, hardness of hearing. In the first, the patient cannot hear a distant noise, and especially high tones; but he can perceive, though, it is true, not in a very distinct manner, articulated sounds, when the voice is a good deal raised. In the second degree, he hears and distinguishes both high and low tones very well, and also words, but only when the voice is somewhat raised.

These two cases are better understood, inasmuch as it is tolerably well ascertained, that the immediate cause of the infirmity is some alteration in that part of the organ which serves as a conductor

for the vibrations of sound, or else an increased sensibility of the nerve, all the internal ear being in other respects right.

Amongst alterations of the conducting parts of the organ, Rosenthal comprehends:

1. A total obliteration of the meatus auditorius externus, its imperforation, or complete absence. These cases may almost always be detected by a superficial examination, the patient only hearing when some solid bodies are placed between his teeth, while his dull perception of sounds does not appear to be much lessened when the ear is covered.

2. Diseases of the cavity of the tympanum, as inflammation of its membranous lining, caries of its parietes, or collections of blood, pus, or other fluid, in its cavity. Rosenthal thinks there can be no doubt, that inflammation and suppuration in the tympanum are much more frequent than is generally supposed, the former affection being often mistaken for a slight attack of rheumatism. In dissecting aged subjects, he has frequently found the membrane of the tympanum thickened and opaque, and he could only impute this appearance to previous inflammation.

After detailing a case illustrative of the symptoms of inflammation within the tympanum, and a few observations on caries and collections of fluid in the cavity, Rosenthal notices the *hardness of hearing, connected with nervous irritability*, in the treatment of which case, he insists upon the advantage that would result from a knowledge of the particular species of morbid excitement prevailing in the patient. But, as nothing very certain can be made out on this point, and only conjectures can arise from dissections of bodies, that the affection consists either in a determination of blood to the part, or in a partial paralysis of the auditory nerve, the exact nature and form of which are quite incomprehensible, it is absolutely necessary to attend solely to the diagnosis of the nervous affection in general. This diagnosis will be facilitated, 1st, If the patient has been previously very sensible to the impression of certain tones, or sound in general; 2ndly, If the power of hearing has been lost all on a sudden, without any mark of inflammation; 3rdly, If the affection coincides with other nervous disorders.

3. *Alteration or Diminution of Hearing.*—Between the most perfect hearing, congenital or acquired, and this point of diminution of the faculty of hearing, Rosenthal observes, there are a great many degrees, the cause of which is the most difficult to comprehend, as the circumstances of structure, which enable every part to perform its functions with freedom and perfection, are not yet made out. If, says he, it were in our power to determine what is truly the regular structure of each part, we should then be furnished with a means of judging correctly of the anomalies of function, the changes in which would be indicated quite as clearly, as in the eye, by shades of organisation, absolutely in the same way as we judge of the modifications, which the image of objects must undergo at the bottom of the ocular mirror, by the greater or less convexity of the cornea, or lens, or the consistence of the other humours.

In the present state of physiological and pathological knowledge of the ear, therefore, Rosenthal conceives, that little can be attempted with respect to a scientific classification of these cases of

altered, or diminished hearing. As the cavity of the tympanum and its contents are the parts which have principal influence over the intensity of sound, and a great share in the propagation of articulated sounds, their faulty condition must here be chiefly the subject for consideration. And, amongst their numerous defects, traced by dissection, and already specified in the foregoing columns, Rosenthal particularly calls the attention of the reader,

1. To alterations of the membrane of the tympanum, whether proceeding from congenital malformation, or situation, or from thickening, ossification, perforation, or laceration of the same part.

2. The lodgment of fluid in the cavity of the tympanum, more frequently produced, than is commonly supposed, by obstruction of the Eustachian tube. In most new-born infants, Rosenthal has also found the cavity of the tympanum filled with a thick, almost gelatinous fluid, which for some days is not absorbed, and is probably the cause of the indifference, evinced by new-born children, to sounds, which are even so intense as to be offensive to the ears of an adult.

3. Alterations of the membrane of the fenestra rotunda, such as its imperfect formation, or erroneous situation, its thickened state, &c.

Mr. Toynbee has given ample details of the pathological conditions of the ear. But, it is remarked by Rosenthal, that as the difference in the intensity of sound may occasion a modification in the sensations of the ear, the merely conducting parts of the auditory apparatus must not be forgotten, as the external ear and the meatus auditorius externus, which regulate the quantity of sonorous waves striking the auditory nerve. However, the malformations of the meatus and the state of the ceruminous secretion within it, are observed by Kritter and Lentin (*Ueber das schwere Gehör*, l. xix. Leipz. 1794) to have more effect on the hearing, than defects of the auricle itself, the whole of which, as we have stated, may be lost without any material deafness being produced. Lastly, Rosenthal calls our attention to the nervous action, or influence, which, whether too much raised, or depressed, may equally render the hearing dull; and some useful information may for the most part be derived from attending to the patient's general sensibility.

ECCHYMOSIS (from ἐκχύω, to pour out).

A swelling, attended with a livid or blue colour of the skin, and produced by blood extravasated in the cellular tissue.

The causes of ecchymosis are falls, blows, sprains, &c. which occasion a rupture of the small vessels on the surface of the body, and a consequent effusion of blood, even without any external breach of continuity. Ecchymosis is one of the symptoms of a contusion. (See CONTUSION.) A considerable ecchymosis may originate from a very slight bruise, when the ruptured vessels are capable of pouring out a large quantity of blood, and particularly when the parts contain an abundance of loose cellular substance. In general, ecchymosis does not make its appearance immediately after the blow or sprain, and sometimes not till several hours after the application of the violence; at least, it is not till this time that the black, blue, and livid colour of the skin is most conspicuous. A black eye, which is only an ecchymosis, is always more disfigured six or eight hours after the receipt of the blow, than at an earlier period.

A common ecchymosis will generally yield to discutient lotions, and purgatives. The best topical applications are vinegar, the lotio ammoniæ hydro-chloratis; spirit. vin. camph. and the liquor ammon. acet.

The object is to prevent inflammation, and to promote the absorption of the extravasated fluid.

I have seen such success attend the practice of dispersing collections of extravasated blood by means of absorption, that I consider the plan of evacuating it by an incision seldom necessary. When an opening is made, and air is admitted, the portion of blood, which cannot be pressed out, soon putrefies, and extensive inflammation and suppuration are the frequent consequences. A man, in going down one of the staircases at the King's Bench, fell, and suffered a contusion over the sacrum, where a tumour, from effused blood, soon formed, almost as large as his head. The

blood was completely absorbed in a few weeks, without any suppuration having taken place. Mild antiphlogistic treatment, cold evaporating lotions and purgatives, were the only means employed. A man was brought into the University College Hospital, Oct. 1, 1836, with a lacerated wound of the scrotum, protrusion of both testes, a fracture of the right femur in its upper third, and a copious extravasation of blood from external violence applied to the left hip. The quantity of blood, effused after a time, was calculated to be not less than three or four quarts. I scarcely expected to succeed in dispersing the whole of it; yet, in about two months, every particle of it was absorbed.

The quick and powerful action of the absorbent vessels in removing extravasations of blood, can now be no longer called in question, when we daily see it proved in modern practice, that the largest aneurismal swellings are thus speedily diminished and removed, after the operation of tying the arteries, from which such tumours arise.

I wish, however, the preceding observations merely to convey a general condemnation of the practice of opening swellings containing extravasated blood; for no surgeon is more assured than I am, that there are particular exceptions, in which the plan is highly proper and necessary. Thus, whenever a case of extensive ecchymosis, or a large tumour of extravasated blood, either excites suppuration, or creates excessive pain from distension, it is better to practise a free opening. So it sometimes happens, in aneurism, that the skin gives way over the tumour after the artery has been tied, and some of the blood escapes; but the remainder putrefies, and soon becomes blended with purulent matter in the sac. Here the making of a free incision into the swelling for the discharge of its irritating contents, with due attention to every caution delivered in the article ANEURISM, will often be followed by beneficial effects.

[ECRASEUR. This instrument consists of a handle and steel canula, in the interior of which are two grooves opposite each other, for the passage of a jointed chain somewhat resembling a chain-saw, but without teeth, the edge being blunted but not serrated. From the extremity of the canula a loop of the chain as long as may be required projects, which is passed around the tumour or other body to be removed, and is gradually tightened by the drawing in of the links by means of a rack and pinion. A modification of the instrument has been constructed, having a handle and steel cylinder, along the side of which there is an opening, and at the extremity a flattened ring through which a loop of the chain before described passes, one end of it being attached to the top of the cylinder, the other to a piece of metal projecting through the opening at the side of the instrument. At the handle, there is a wheel attached to a long screw which passes into the interior of the cylinder, and by its revolutions acts upon the piece of steel to which the chain is attached. The advantage of the latter instrument is that the pressure upon the tumour is gradual, instead of being in jerks as with the rack and pinion movement; and also the chain being external to the cylinder, the instrument is not so liable to become clogged by matter getting into the interior. Charrière has combined the advantage of a straight and curved instrument by making several extremities screw on to one

handle. Chains too of various calibres are fitted to the instrument, enabling us to employ that size best suited to the operation to be performed. The chain attached to the curved extremity has been made with a degree of curves in its links, so that besides being more easily applied to a tumour in a deep passage, as the vagina or rectum, it adapts itself to the channel of the instrument more easily than a straight chain, and is consequently less apt to be broken when drawn home. The mode of attaching the ends of the chain is also rendered more simple and satisfactory, and as traction can if necessary be made on both ends at once, the power is much increased. Strong wire or a soft cord of hemp have been occasionally used instead of the jointed chain.

The *ecraseur* has been used by Chassaignac of Paris, since the year 1850; and it is intended for the removal of morbid growths on those parts of the body from which, on account of their vascularity, considerable hæmorrhage may be expected, and in such cases it has been thought that it would supersede the use of the knife and the ligature. Its action, although much slower than that of the knife, is considerably more rapid than that of the ligature, which divides the tissues by the process of gangrene it induces, and consequently there is for some time a putrid mass at the part constricted, subjecting the patient to the danger of purulent absorption. On the other hand, the *ecraseur* acts directly by first condensing the tissues, and subsequently dividing them with extreme regularity. When it acts upon an artery, it first divides the two internal coats which are folded up in such a manner as to plug the vessel; the closure is assisted by the agglutination of the outer coats before they are divided, and after separation has been effected the closure is so perfect that the channel cannot be opened, even by blowing forcibly through it.

In some experiments which have been made at the Veterinary School near Paris, the carotids of sheep have been divided without loss of blood—this will be readily understood on considering the small amount of hæmorrhage usually following contused and lacerated wounds. The operations for which the *ecraseur* is suitable are, as before observed, those in which, from the vascularity of the part, much hæmorrhage may be expected, such as cancer of the tongue, hæmorrhoids, prolapse of the rectum, uterine polypi, cancer of the neck of the uterus, varicocele, sarcocele, &c. &c. It is also necessary that the part to be removed should be pedunculated; where this is not the case the tumour should be raised up well, and several needles passed under it at different angles; a ligature should be tied behind these, and thus form a peduncle for the chain to pass round, or the base of the tumour may be transfixed by a needle and double thread, thus pedunculating each lateral half.

In removing the tongue two *ecraseurs* will be required; the chain of one is introduced into the mouth by means of a needle passed through an incision below the chin, in the same way as Cloquet applies ligatures for accomplishing the same end. The root of the tongue is thus encircled and cut from above downwards. The second chain introduced by the mouth is laid in the incision made by the first across the base, and is made to divide all the attachments of the organ from be-

hind forwards. Half an hour is sufficient to accomplish this operation. Half the tongue may be removed by passing two chains through the tongue at the angle of union of the diseased and healthy structures, and making one chain sever the parts from behind forwards while the second cuts its way out at right angles to the first.

For the removal of piles, the tumour is seized with a vulsellum and drawn out, when if small a ligature is simply thrown round its base, and the chain applied, or if larger a double thread is carried through its base and tied so as to constrict it in two halves, or a needle may be left transfixing its base, and a ligature applied behind it. When the anus is entirely surrounded by vascular piles, Chassaignac removes the whole at one grasp by introducing a pair of his diverging forceps within the orifice, drawing it well out, and applying a ligature, so as to pedunculate the part, and then using the chain. A bougie must, in this case, be introduced within twenty-four hours, and that with great gentleness, to prevent tearing, so as to ensure the patency of the gut, which is apt to be obliterated by the strong compression of the chain. It is necessary, also, that the bowels should be kept quiet by opium for twenty-four hours. In the operation for the cure of varicocele it is necessary to pass three needles beneath and at right angles to the veins, taking care that the lowest one does not pierce the tunica vaginalis. A ligature must be applied behind the needles, and thus a peduncle formed for the chain to encircle. For removing the testicle, either one or two instruments may be used; if one, the scrotum must be drawn up around the organ to be removed, and the chain applied above the testicle; but if two are used it will be necessary to introduce a trocar and canula through the scrotum above the testis and behind the cord. The trocar being withdrawn, two chains are passed through the canula, which is then removed, and each chain attached to its apparatus; one will divide the scrotum longitudinally, the other will divide the cord and tissues above the testicle.

The *ecraseur* has been very much lauded by its inventor, Chassaignac; but although it has been tried in England for four years, its success is not so certain. There is no doubt that it may be useful in the removal of piles, polypi, and such erectile or malignant growths as could not be removed by the knife without probability of dangerous hæmorrhage; and in such cases its superiority over the ligature is the time gained and the non-liability to putrid or purulent absorption. (*T. Wakley.*)

ECTHYMA (*ἐχθυμιάω*, *exhalo*, or from *ἐχθύειν*, to break with fury). A term, employed by the ancients, and revived by Willan, to denote an inflammation of the skin, principally characterised by large or phlyzaceous pustules of the skin, in one or several regions of the body. The term *phlyzaceous* was applied by Willan to pustules which are large, elevated on a hard circular base, of a bright red colour, and succeeded by a thick indurated scab, of a dark colour.

ECTROPION (from *ἐκτρέπω*, to turn) An eversion of the eyelids.

One case is produced by an unnatural swelling of the lining of the eyelids, which not only pushes their edges from the eyeball, but also presses them so forcibly, that they become everted: another, arises from a contraction of the skin of the eyelid, or its vicinity, by which means the edge of the eyelid is first removed to some distance from the eye, and afterwards turned completely out, together with the whole of the affected eyelid.

The morbid swelling of the lining of the eyelids, which causes the first species of ectropion (putting out of present consideration a similar affection incidental to old age), arises mostly from a congenital laxity of this membrane, afterwards increased by obstinate chronic ophthalmia in relaxed, unhealthy subjects; or else the disease originates from purulent ophthalmia affecting the eyes.

While the disease is confined to the lower eyelid, as it most commonly is, its lining may be observed rising in the form of a semilunar fold, of a pale red colour, like the fungous granulations of wounds, and intervening between the eye and eyelid, which latter it in some measure everts. When the swelling is occasioned by the lining of both the eyelids, the disease assumes an annular shape, in the centre of which the eyeball seems sunk, while the circumference of the ring presses, and everts the edges of the two eyelids so as to cause both great uneasiness and deformity. In each of the above cases, on pressing the skin of the eyelids with the point of the finger, it becomes manifest that they are very capable of being elongated, and would readily yield, so as entirely to cover the eyeball, were they not prevented by the intervening swelling of their membranous lining.

Besides the considerable deformity, which the disease produces, it occasions a continual discharge of tears over the cheek, and, what is worse, a dryness of the eyeball, frequent exasperated attacks of ophthalmia, incapacity to bear the light, and, lastly, opacity and ulceration of the cornea.

The second species of ectropion, or that arising from a contraction of the integuments of the eyelids, or neighbouring parts, is not unfrequently a consequence of puckered scars, produced by the confluent small-pox, deep burns, or the excision of cancerous or encysted tumours, without saving a sufficient quantity of skin; or, lastly, the disorder is the effect of malignant carbuncles, or any kind of wound attended with much loss of substance. Each of these causes is quite enough to bring on such a contraction of the skin of the eyelids, as to draw these parts towards the arches of the orbits, so as to remove them from the eyeball, and turn their edges outward. No sooner has this circumstance happened, than it is often followed by another one equally unpleasant, namely, a swelling of the internal membrane of the affected eyelids, which afterwards has a great share in completing the eversion. The lining of the eyelids, though trivially everted, being continually exposed to the air, and to irritation from extraneous substances, soon swells, and rises up, like a fungus. One side of this fungus-like tumour covers a part of the eyeball; the other pushes the eyelid so considerably outward, that its edge is not unfrequently in contact with the margin of the orbit. The complaints, induced by this second species of ectropion, are the same as those brought on by the first; and, in both cases, when the dis-

ease is inveterate, the fungous swelling becomes hard and callous.

In the first species of the disease, the skin of the eyelids and adjoining parts is not deformed with scars; and by pressing the everted eyelid with the point of the finger, the part would with ease cover the eye, were it not for the intervening fungous swelling. But, in the second, besides the obvious cicatrix and contraction of the skin of the eyelids or adjacent parts, when an effort is made to cover the eye with the eyelid, by pressing upon the latter part with the point of the finger, it does not give way, so as completely to cover the globe, or it does not move in the least from its unnatural position, by reason of the integuments of the eyelids having been so extensively destroyed, that their margin is adherent to the arch of the orbit.

Mr. Guthrie instances a case, depending on chronic inflammation, accompanied with contraction of the integuments of the eyelid, but *without any manifest cicatrix*. It is described as usually taking place after a long continuance of *lippitudo*, and proceeding from the excoriation, contraction, and hardening of the skin, "the result of the passage of the vitiated secretions over it, and which, by dropping on it, increase the irritation." (*Operative Surgery of the Eye*, p. 50—55.) This form of the disease is rarely attended with such a thickening of the inner membrane of the eyelid, as to need removal with the knife or scissors; for it subsides with the removal of the complaint. (P. 60.)

According to Scarpa, the cure of ectropion cannot be accomplished with equal perfection in both its forms, the second species being, in some cases, absolutely incurable. For, as in the first species of ectropion, the disease only depends upon a morbid thickening of the internal membrane of the eyelids, and the treatment merely consists in removing the redundant portion, art possesses many efficacious means of accomplishing what is desired. But, in the second species, the chief cause of which arises from the loss of a portion of the skin of the eyelids or adjacent parts, which loss no known artifice can restore, surgery is not capable of effecting a perfect cure. The treatment is confined to remedying, as much as possible, such complaints as result from this kind of eversion, and this can be done in a more or less satisfactory manner, according as the loss of skin is little or great. Cases in which so much skin is deficient that the edge of the eyelid is adherent to the margin of the orbit, Scarpa abandons as incurable. How far the case can be rectified, he thinks, may always be estimated by remarking to what point the eyelid admits of being replaced, on being gently pushed with the end of the finger, towards the globe of the eye, both before and after the employment of such means as are calculated to effect an elongation of the skin of the eyelid; for it is to this point, and no further, that art can reduce the everted part, and permanently keep it so replaced.

When the first species of ectropion is recent, the fungous swelling of the lining of the eyelid not considerable, and, consequently, the edge of the eyelid not much turned out, and in young subjects (for in old ones the eyelids are so flaccid, that the disease is irremediable), Scarpa prefers destroying the fungous surface of the internal membrane of the eyelid by the repeated application of the nitrate of silver. Mr. Guthrie touches the fungous portion of the conjunctiva every four days,

with a probe dipped in sulphuric acid, and gently applies every day, or every second day, the sulphate of copper, at the same time not omitting some minor remedies, which he also employs in cases proceeding from contraction of the skin independent of any cicatrix, and which I shall presently notice. (*Operative Surgery of the Eye*, p. 70.) In recent cases, where the patient is weak and irritable (or a child), Beer commences the treatment with simply applying every day the tincture of opium, which, after a time, is strengthened by the addition of naphtha. To the relaxed conjunctiva he afterwards applies escharotic eye-salves, and lastly, the nitrate of silver, and muriate of antimony. When the part is hard and callous, the caustic is preceded by scarifications. (*Lehre, &c.*, b. ii. p. 136.)

For remedying the inveterate form of the first species of the disease, Beer and Scarpa are advocates for cutting away the whole of the fungous swelling closely from the inside of the eyelid. The following is Scarpa's description of the operation:—

The patient being seated, with his head a little inclined backward, the surgeon, with the index and middle finger of his left hand, is to keep the eyelid steadily everted; and holding a small pair of curved scissors with convex edges, in his right, he is completely to cut off the whole fungosity of the internal membrane of the eyelid, as near as possible to its base. The same operation is then to be repeated on the other eyelid, should that be affected with the same disorder. If the excrescence should be of such a shape, that it cannot be exactly included within the scissors, it must be raised with a forceps, or a double hook, and dissected off at its base, by means of a small bistoury with a convex edge. The bleeding stops of itself, or as soon as the eye has been bathed with cold water. The surgeon is then to apply two small compresses, one put on the upper, the other on the lower arch of the orbit, and over these the uniting bandage, in the form of the monocus, or so as to compress and replace the edges of the everted eyelids, in order to make them cover the eye. On the first removal of the dressings, which should take place in twenty-four or thirty hours after the operation, the surgeon will find the whole, or almost the whole of the eyelid, in its natural position. The wound on the inside of the eyelid should then be washed twice a day with simple water or barley-water. If, towards the end of the cure, it should assume a fungous appearance, or the edge of the eyelid seem to be too distant from the eyeball, the wound on the inside of the eyelid must be rubbed several times with the nitrate of silver, for the purpose of destroying a little more of the membranous lining, so that, when the cicatrization follows, a greater contraction of it may take place, and the edge of the eyelid be drawn still nearer the eye.

In England, the excision of the fungous thickened portion of the conjunctiva, has mostly been relinquished for the employment of caustic. The difficulty of dissecting off every particle of the fungus renders the practice of excision less certain than the treatment with caustic. Scarpa confesses its occasional failure, and the necessity of then having recourse to the latter plan. Demours also lets the employment of caustic follow the use of the knife. (*Mal. des Yeux*, p. 93.) In ectropion from a relaxed fungous state of the conjunctiva, the

consequence of purulent ophthalmia, Dr. Vetch begins with a light careful application of the nitrate of silver to the whole granulated villous surface. The everted part is then to be returned, and secured in its place with a compress, and straps of plaster and a bandage. Every time the eye is cleaned, the same things are to be repeated, and, in the course of a few days, the tendency to protrude will disappear. (*On Diseases of the Eye*, p. 228.)

In the species of ectropion produced by an accidental contraction of the skin of the eyelids, or neighbouring parts, Scarpa observes, that, if a contraction of the integuments has proved capable of everting the eyelid, the excision of a piece of the internal membrane of the part, and the cicatrix which will follow, must also be capable, for the same reason, of bringing back the eyelid into its natural position. But, since nothing can restore the lost skin, the shortened state of the whole eyelid, in whatever degree it exists, must always continue, even after any operation the most skilfully executed. Hence the treatment of the second species of ectropion will never succeed so perfectly as that of the first, and the replaced eyelid will always remain shorter than natural, in proportion to the quantity of integuments lost. It is true that, in many cases, the eversion seems greater than it actually is, in regard to the small quantity of skin lost or destroyed; for, when the disease has once begun, though the contraction of the skin may be trivial, in consequence of the little quantity of it deficient, still the swelling of the lining of the eyelid, which never fails to increase, at last brings on a complete eversion of the part. In these cases, the cure may be accomplished with such success as is surprising to the inexperienced; for, after the fungous swelling of the internal membrane of the eyelid has been cut off, and the edge of the part approximated to the eyeball, the shortening of the eyelid remaining after the operation is so trivial, that it may be considered as nothing in comparison with the deformity and inconvenience occasioned by the ectropion. Whenever, therefore, the retraction of the skin of the everted eyelid, and the consequent shortness of it, are such as not to prevent its rising again and covering the eye, if not entirely, at least moderately, Scarpa directs the surgeon to cut away the internal membrane of the everted eyelid, so as to produce a loss of substance on the inside of it. In inveterate cases of ectropion, in which the lining of the eyelids has become hard and callous, Scarpa applies to the everted eyelid, for a few days before the operation, a soft bread and milk poultice.

The division of the cicatrices, which have given rise to the shortening and eversion of the eyelid, as Scarpa observes, does not procure any permanent elongation of this part, and consequently it is of no avail in the cure of the present disease. Fabricius ab Aquapendente, who well knew the inutility of making a semilunar cut in the skin of the eyelids, for the purpose of remedying their shortness and eversion, proposes, as the best expedient, to stretch them with adhesive plasters applied to them and the eyebrow, and tied closely together. Whatever advantage may result from this practice, the same degree of benefit may be derived from using, for a few days, a bread and milk poultice, afterwards oily embrocations, and, lastly, the uniting bandage, so put on as to stretch the shortened eyelid in an opposite direction to that produced by the cicatrix;

a practice which Scarpa thinks should always be carefully tried before the operation is determined upon.

The surgeon, with a small convex-edged bistoury, is to make an incision of sufficient depth into the internal membrane of the eyelid, along the tarsus, carefully avoiding the situation of the puncta lachrymalia. Then, with a pair of forceps, he should raise the flap of the divided fungous membrane, and continue to detach it with the bistoury from the subjacent parts, all over the inner surface of the eyelid, as far as where the membrane quits this part, to be reflected over the front of the eye, under the name of *conjunctiva*. The separation being thus far accomplished, the membrane is to be raised still more with the forceps, and cut off with one or two strokes of the scissors, at the lowest part of the eyelid. The compresses and bandage to keep the eyelid replaced, are to be applied as above directed. On changing the dressings, a day or two after the operation, the eyelid will be found, in a great measure, replaced, and the disfigurement which the disease caused greatly amended. The operation is occasionally, though rarely, followed by bad symptoms, such as vomiting, violent pain, and inflammation. However, should they occur, the vomiting may be relieved by means of an opiate clyster, and as for the pain and inflammation, attended with great tumefaction of the eyelid operated upon, these complaints may be cured by applying a poultice, or bags filled with emollient herbs, at the same time employing internal antiphlogistics, until the inflammation and swelling have subsided, and suppuration has commenced on the inside of the eyelid, on which the operation has been done. After this, the treatment is to consist in washing the part twice a day, with water, or barley-water, and lastly, in touching the wound a few times with the nitrate of silver, in order to keep the granulations within certain limits, and to form a permanent cicatrix, proper for maintaining the eyelid replaced.

Juengken describes a plan, which has been adopted by Jaeger, and was practised a hundred years ago by Platner (*Instit. Chir.* § 582), and even recommended a century before this author, by our countryman, Bannister. Heister and Dionis notice it still more circumstantially. (See *Middlemore, On Dis. of the Eye*, vol. ii. p. 787.) It consists in detaching the everted eyelid from the cheek, or superciliary ridge, at every point, excepting the angles, by introducing a sharp-pointed double-edged knife, through the conjunctival surface, near the inner angle, bringing it out through the skin, and conveying it across to the outer angle. A portion of the thickened conjunctiva, or a triangular piece of the lid, may be first removed, if necessary. The detached lid is then to be accurately fixed, in contact with the globe, and the skin of the cheek drawn towards the eye, and kept in that position with adhesive plaster, compresses, and bandage. (*Handbuch*, &c. p. 696.) Dieffenbach makes an incision through the skin and orbicularis, nearly parallel to the edge of the lower lid, beginning two or three lines from one angle, and terminating at the same distance from the other. It is one line from the edge of the lid at its two ends, and two or three lines in the middle. He turns up the small flap of skin, and dissects through the lid to the conjunctiva, which he divides to the extent of the external wound. With a

hook he draws the external margin of the divided conjunctiva into the wound of the skin, and keeps it and the integuments together with sutures. (See *Chir. Erfahrungen über die Wiederherstellung Zerstorter Theile*, &c. von J. F. Dieffenbach, p. 127. Berlin, 1830.)

In cases in which the eversion is considerable, Sir W. Adams never found the simple excision of the fungus sufficient to effect a radical cure, and he therefore tried a new mode of operating. In his first attempts he employed a small curved bistoury, the point of which he carried along the inside of the eyelid, at its outer angle, downwards and outwards, as far as the point of reflection of the conjunctiva would admit. He then pushed it through the whole substance of the everted eyelid and its integuments, and cut upwards through the tarsus, making an incision nearly half an inch in length. With a curved pair of scissors he next snipped off a piece of the edge of the tarsus, about one-third of an inch in width, and he afterwards removed with the same instrument the whole of the diseased conjunctiva. When the bleeding had ceased, Sir W. Adams passed a needle and ligature through the whole substance of the two divided portions, and brought them as accurately into contact as possible. Finding, however, that too much integument had been left at the lower part of the incision, he employed, in future operations, instead of the scalpel, a pair of straight scissors, with which he cut out an angular piece of the lid, resembling the letter V, with its broad interval towards the ciliary edge of the lid. Latterly, Sir W. Adams found it advantageous to leave about a quarter of an inch of the lid adjoining its external angle; and after shortening the part as much as necessary, he brought the edges of the incision together with a suture. (See *Practical Obs. on Ectropion*, &c. p. 4 and 5. Lond. 1812.)

That this operation will cure the ectropion, caused by the contraction of cicatrices, or produce great improvement, the experience of Mr. Travers confirms. (*Synopsis of the Diseases of the Eye*, p. 235.) Mr. Guthrie also acknowledges that it may be highly useful in the ectropion from the contraction of a cicatrix. (*On the Operative Surgery of the Eye*, p. 71.) The contracted scar must be divided, in addition to the other proceedings.

In the form of ectropion, arising from a hardened and contracted state of the integuments of the eye, but without any cicatrix, the indications seem to Mr. Guthrie to be: 1st, To relieve the contraction of the skin externally; 2ndly, To restore and retain the eyelid in its proper situation, until the unnatural curvature of the cartilage has been overcome, and the chronic inflammation removed. For fulfilling the first indication he recommends washing the external parts with warm water, so as to leave the skin as clean as possible. It is then to be carefully dried, and repeatedly anointed with the ung. zinci, for three or four days. Being thus protected from the irritation, it becomes softer, and in a favourable state to yield to mild extension. For accomplishing the second indication, Mr. Guthrie applies the sulphuric acid; the eyelid having been cleansed so as to prevent its slipping, the conjunctiva is to be gently wiped dry, and everted as much as possible, so that the part where it begins to be reflected over the eyeball may be seen. An assistant is to raise the upper eyelid a little, and the patient to look upwards. The blunt

end of a common silver probe is then to be dipped in the sulphuric acid, and rubbed over the conjunctiva, so that every part of it may be touched with the acid. The round point of the probe is to be carried as far as where the membrane begins to be reflected over the eyeball, but no further. The punctum lachrymale, caruncle, and semilunar fold are to be avoided; but the external angle, as well as every other part, except what is reflected over the eye, is to be carefully rubbed. The acid will turn the touched portion of the conjunctiva white; and in order to prevent the acid from affecting the eyeball, a stream of water is now to be directed over the eyelid with an elastic gum syringe. If the conjunctiva should not be turned sufficiently white, the application may be repeated. The use of the acid is to be repeated every fourth day; "and, when applied in the manner directed, it does not cause a slough, but a general contraction of the part, which is, however, only perceptible after two or three applications, by its effect in inverting the lid, which gradually begins to take place. After six or eight applications, the cure will be more than half accomplished, and, in most cases of this species of eversion, the thickening of the conjunctiva will have subsided." The ung. zinci is to be constantly applied to the skin, and the ung. hydrarg. nitr. in the proportion of one part to four or six of the ung. cetacei, to the edge of the eyelid. After the eyelid has returned two-thirds of the way towards its natural position, the intervals between the applications of the acid must be longer, lest the contraction within the eyelid be carried too far, and an inversion of it produced. After the eversion has been cured, the lippitudo may yet partly remain, and demand the use of the ung. hydrarg. nitr., or other gentle stimulants.—

ECZEMA, or ECZESMA (from ἐκζέω, to boil out), is characterised by an eruption of small vesicles on various parts of the skin, usually close, or crowded together, with little or no inflammation round their bases, and unattended by fever. It is not contagious. (*Bateman's Synopsis*, p. 250. ed. 3.) There are several varieties of this disease, the most remarkable of which is the *eczema rubrum* from the irritation of mercury. This form is attended with quickened pulse and a white tongue; but the

stomach and sensorium are not materially disturbed. (See MERCURY.)

EFFUSION, in surgery, means the passage of any fluid out of the vessel, or viscus, naturally containing it, and its lodgment in another cavity, the cellular tissue, or the substance of parts. Thus, when the chest is wounded, blood is sometimes effused from the vessels into the cavity of the pleura; in false aneurism, the blood passes out of the artery into the cellular tissue; in retention of urine, this fluid, after a time, flows from the bladder and urethra into the cellular tissue of the perinæum and scrotum; and, when great violence has been applied to the skull, blood is often effused upon, or in the substance of, the brain. Effusion also sometimes signifies the separation of fibrine, or a serous fluid from the vessels by the process of secretion, or some action of the vessels analogous to it. (See EXTRAVASATION.)

ELECTRICITY. Among the aids of surgery, electricity once held a conspicuous and important situation. It has, however, met with a fate, not unusual with remedies too much cried up and too indiscriminately employed; that of having fallen into an undeserved degree of neglect. Whatever its effects may be on the system, it certainly possesses this advantage over other topical remedies, that it may be made to act on parts very remote from the surface. Electricity, as a topical remedy for surgical diseases, is chiefly tried in amaurosis, deafness, some chronic tumours, and abscesses, weakness from sprains, or contusions, paralysis, &c. In suspended animation, electricity is sometimes an important auxiliary for the restoration of the vital functions. (See *J. Curry's Obs. on Apparent Death*, &c. ed. 2, 1815.)

ELEVATOR. An instrument for raising depressed portions of the skull. Besides the common elevator, now generally preferred by all the best operators, several others have been invented; as, for instance, the tripod elevator, and another, which was first devised by J. L. Petit, and afterwards improved by M. Louis.

EMBROCATION. (See LINIMENTUM.)

EMBRYOTOMIA (from ἔμβρυον, the fœtus, and τέμνω, to cut). The operation of cutting into the womb, in order to extract the fœtus. (See CÆSAREAN OPERATION.)

EMPHYSEMA (ἐν, into, φυσίω, I inflate). A swelling produced by the presence of atmospheric air, or of any other gaseous fluid, which has insinuated itself into, or been formed in, the cellular tissue. Emphysematous swellings are divided into two classes; one, the *traumatic*, in which they originate from a wound of some part of the organs of respiration; and another, the *idiopathic* or *spontaneous*, where they proceed either from chemical decomposition, or from secretion or internal pathological causes, the nature of which is obscure. In the latter class have been arranged *emphysema of the lungs*, a subject on which the researches of Laennec throw important light; and certain cases, where, in consequence of decomposition, gas is found under the mucous membrane of the digestive canal. (See *L. J. Bégin in Dict. de Méd. et de Chir. Pratiques*, t. vii. art. *Emphyseme*.)

With regard to *traumatic emphysema*, or that originating from a breach in the air-passages, sometimes it arises from a manifest, or concealed wound of the lungs, bronchi, trachea, or larynx; some-

times it follows a rupture of the air-cells, or passages, by the air itself. One common cause is a fractured rib, by which the air vesicles of the lungs are wounded, so that the air escapes from them into the cavity of the thorax. But, as the rib, at the moment of its being fractured, is pushed inwards, and wounds the pleura, which lines the ribs and intercostal muscles, part of the air most commonly passes through the pleura, into the cellular tissue, on the outside of the chest, and thence is diffused through the same over the whole body, so as to inflate it sometimes in an extraordinary degree.

Emphysema is frequent after a fractured rib, in cases where there is a wide laceration of the lungs, and no exit for the air; it is less frequent in large wounds with a knife, or broad sword, because the air has an open and unimpeded issue; it is again more frequent in deep stabs with bayonets, or small swords; and it often follows gunshot wounds of the chest, particularly those in which the ribs are splintered. (See *J. Bell, On Wounds of the Breast*, p. 265.)

Emphysema has also been known to arise from a rupture of the larynx and trachea, produced by a blow, or kick, as is exemplified in the case reported by Dr. L. O'Brien. (See *Edin. Med. and Surg. Journ.* No. lxxii.)

The emphysematous swelling, wheresoever situated, is easily distinguished from œdema, or anasarca, by the crepitation which occurs on handling it, or by the noise, resembling that which is heard on compressing a dry bladder half filled with air. The tumour is colourless and free from pain. It does not form especially in depending parts, though by pressure it may be made to change its situation. It is elastic, that is to say, it may be pressed down, but it rises up again as soon as the pressure is discontinued. The swelling never retains the impression of the end of the finger, or, in the language of surgery, never *pits*. The part is not heavy. The tumour first makes its appearance in one particular place; but soon extends, and causes an extraordinary distension of the skin. (*Richter's Anfangsgr. der Wundarzn.* b. i. p. 451.)

In bad cases, the patient complains of a considerable tightness of the chest, with pain, chiefly in the situation of the injury, and great difficulty of breathing. This obstruction of respiration gradually increases, and becomes more and more insupportable. The patient soon finds himself unable to lie down in bed, and cannot breathe, unless when his body is in the upright posture, or he is sitting a little inclined forward. In vain he endeavours to articulate a few words; at each inspiration a fresh column of air escapes from the breach in the lung, and renders his condition worse. Together with these symptoms, there is sometimes bloody expectoration, announcing a deep wound of the lungs. (See *Case by Dupuytren, in Clin. Chir.* t. i. p. 117.) The countenance becomes dusky and puffed. The pulse, at first weak and contracted, becomes afterwards irregular. The extremities grow cold; and, if the patient continue unrelieved, he soon dies suffocated.

The diagnosis is not always free from obscurity, especially when emphysema is deeply seated, without any external tumour. An accumulation of air in one of the cavities of the pleura, however, is

attended with an elevation and expansion of the ribs on the injured side, a clear sound on percussion, and excessive difficulty of breathing. In one example, where the fifth and sixth ribs were broken, there was, in addition to other symptoms already enumerated, an internal hissing sound at each expiration. (*Bégin, Dict. de Méd. et de Chir. Pratiques*, t. vii. p. 117.) For other symptoms and signs of the presence of air in the cavities of the pleura, see PNEUMO-THORAX.

The wound of the parietal pleura and intercostal muscles may sometimes be too small to suffer the air to get readily into the cellular tissue, and inflate it; in such case a portion of the air may be confined in the cavity of the thorax, so as to compress the lungs, prevent their expansion, and cause the same symptoms of tightness of the chest, quick breathing, and sense of suffocation, which the serous fluid does in hydrophora pectoris or the pus in empyema. (*Hewson, in Med. Obs. and Inq.* vol. iii.)

To understand why the air passes at all out of the wound of the lungs, we must advert to the manner in which inspiration and expiration are naturally carried on. In the perfect state, the surface of the lungs always lies in close contact with the membrane lining the chest, both in inspiration and expiration. The lungs themselves are chiefly passive organs, having only a slight contractile power, depending upon their elasticity. They are incapable, by any action of their own, of expanding and contracting, so as to maintain their external surface always in contact with the inside of the thorax, which is continually undergoing an alternate change of dimensions. Every muscle, that has any share in enlarging and diminishing the capacity of the chest, must contribute to the effect of adapting the volume of the lungs to the cavity in which they are contained, so long as there is no communication between the cavity of the pleura and the external air. In inspiration, the thorax is enlarged in every direction; the lungs are expanded in the same way; and the air, entering through the windpipe into the air-cells of these organs, prevents the occurrence of a vacuum.

But, when a free communication exists between the atmosphere and the pleural cavity, in consequence of a wound, no sooner is this cavity expanded, than the air naturally enters it at the same time, and for the same reasons, that the air enters the lungs through the trachea; in consequence of this the lung itself remains proportionally collapsed. When the thorax is again contracted, in expiration, the air is compressed out of the lung, and also out of the sac of the pleura, through the external wound, if there be a direct one; in which circumstance, the emphysematous swelling is never extensive.

But, in the case of a fractured rib, attended with a breach in the pleura costalis, pleura pulmonalis, and air-cells of the lung, there is no direct communication between the cavity of the chest and the external air; in other words, there is no outward wound in the parietes of the thorax. There is, however, a preternatural opening formed between the air-cells of the lung and the cavity of the chest, and also another one between the latter space and the general cellular tissue of the body, through the breach in the pleura costalis. The consequence is, that when the chest is expanded in inspiration, air rushes from the wound in the surface of the lung,

and insinuates itself between it and the pleura costalis. The lung collapses in proportion, and the place which it naturally occupied, when distended, is now occupied by the air. When, in expiration, the dimensions of the chest are everywhere diminished, the air, now lodged in the sac of the pleura, cannot get back into the aperture in the collapsed lung, because this is already full of air, and is equally compressed on every side, by that which is confined in the thorax. Were there no breach in the pleura costalis, this air could not now become diffused; the muscles of inspiration would next enlarge the chest, remove the pressure from the surface of the wounded lung, more air would be sucked out of it, as it were, into the space between the pleura costalis and pleura pulmonalis, and this process would go on, till the lungs of the wounded side were completely collapsed. But, in the case of a fractured rib, or narrow stab, in which there is also a breach in the pleura costalis, without any free vent outward for the air which gets out of the lung into the cavity of the pleura, as soon as the expiratory powers lessen the capacity of the chest, this air, not being able to pass back through the breach in the collapsed lung, is forced through the laceration, or wound, in the pleura costalis, into the cellular tissue.

It is through the communicating cells of this structure that the air becomes most extensively diffused over the whole body, in proportion as the expiratory muscles continue in their turn to lessen the capacity of the chest, and pump the air, as it were, through the breach in the pleura costalis, immediately after it has been drawn out of the wound of the lung in inspiration. (See *John Bell, On Wounds of the Breast, and Halliday, On Emphysema, 1807.*)

When organised adhesions exist between the pleura costalis and pleura pulmonalis, so as to establish a continuity of textures between the surface of the lung and the parietes of the chest, the comprehension of the mechanism of emphysema is, as Dupuytren remarks, assuredly perfectly simple. The air then passes directly from the interior of the lung into new-organised cellular texture, and thus gets through the parietes of the injured side into the subcutaneous cellular tissue. When there are no adhesions, a part of the air escapes, during inspiration, from the opening in the surface of the lung, and then becomes diffused in the surrounding textures and the cavity of the pleura. Thence it is forced in all directions, as Dupuytren conceives, both by the alternate movements of expansion and contraction of the chest in respiration, and by the effect of its own elasticity; and it is made to enter progressively the cellular tissue of all the internal and external organs. Thus, if the quantity of air drawn out of the lung is considerable, it passes not only into the parietes of the chest and belly, the upper and lower extremities, the interior of the scrotum, the neck and head, but also into the cavity of the pleura, the two mediastina, the pericardium itself, and even into the interlobular cellular tissue of the lungs themselves. (See *Dupuytren, in Clin. Chir. t. i. p. 113. 119.*) In some cases, emphysema is the principal disorder; in others, it is only one of secondary importance, and sometimes not readily ascertained. An example, illustrating this fact, is given by Dupuytren, where the upper fragment of a broken sternum had penetrated the pericardium, and torn the right

ventricle of the heart; and where a considerable quantity of bloody serum and of black blood itself was effused in the right cavity of the pleura; the fourth, fifth, and sixth ribs broken; and their cartilages separated from the sternum. (*Ib. p. 120.*) A case, published by M. Littre, well illustrates the enormous distension of the cellular tissue occasionally produced: on the chest, the swelling was eleven inches thick; on the belly, nine; on the neck, six; and four on other parts. (See *Mém. de l'Acad. des Sciences, 1713.*)

To prove that the confinement of air in the chest is the cause of the dangerous symptoms attending emphysema, Hewson adverts to the histories of some remarkable cases, published by Littre, Mery, W. Hunter, and Cheston. (See *Mém. de l'Acad. Royale des Sciences for 1713; Med. Obs. and Inquiries, vol. ii.; and Pathological Inquiries.*) The same eminent man made several experiments on animals, tending to prove that air in their chests produced great difficulty in breathing, such as occurs in emphysema; and, in one case, which he examined after death, air was actually discharged on puncturing the thorax.

While none of the symptoms denote the extension of emphysema to internal organs, and the quantity of air does not exceed a few cubic inches, the patient is not in danger, so far as this disorder is concerned. But the case is very different when the air has passed not only into all the subcutaneous cellular tissue, but also into that of the internal organs of the chest, and even those of the abdomen; and when, besides such distension of the cellular tissue generally, there is likewise an accumulation of air in the pleural cavity. (See *Dupuytren, Clin. Chir. t. i. p. 112.*)

The passage of air as a complication of fractures, or penetrating wounds of the chest, occurs not only in the subcutaneous or intermuscular cellular tissue, but in any region adjacent to the air passages or cavities. M. Carré has published an instance of air ascending the nasal duct, and rupturing one of the lachrymal canals, when the patient blew his nose. (See *Mém. de Méd. Milit.*) One case of emphysema of the eyelids from a presumed fracture of the horizontal plate of the ethmoid bone, or os unguis, and another from a supposed laceration of the pituitary membrane, used to be related by Dupuytren in his lectures. He also gives the particulars of an emphysema of the temporal region from a fracture of the frontal sinus. In all these examples of emphysema from injury of the upper parts of the respiratory apparatus, the surgeon will notice, in addition to the crepitation, &c. a sudden increase of the swelling whenever the patient coughs or blows his nose. (Vol. cit. p. 123—130.) Here the treatment consists in the application of cold astringent lotions, and the avoidance of everything calculated to make the air escape through the breach into the cellular tissue.

The object of Mr. Hewson's paper is to recommend making an opening in the chest, for the purpose of giving vent to the air confined in that cavity, just as is done for the discharge of pus, in empyema, or of a serous fluid, in hydro pectoris.

In wounds of the lungs, says this author, whether occasioned by fractured ribs, or other causes, when symptoms of tightness and suffocation come on, so far should we be from dreading the emphysematous swelling of the cellular tissue, that we should rather consider it as a favourable symptom,

showing that the air is not likely to be confined in the thorax; and so far should we be from compressing the wound to prevent the inflation, or emphysema, that we should rather dilate it (if not large enough already) or perform paracentesis thoracis. We may judge of the necessity of this operation from the violence of the symptoms, such as the oppressed breathing, &c. For when these are not considerable, and the air passes out of the chest with sufficient freedom, the operation is then unnecessary.

If the disease is on the right side, the best place for performing the operation, says Mr. Hewson, will be on the fore part of the chest, between the fifth and sixth ribs; for there the integuments are thin, and, in the case of air, no depending drain is required. But, if the disease is on the left side, it will be more advisable to make the opening between the seventh and eighth, or eighth and ninth ribs, in order that we may be sure of avoiding the pericardium. As large penetrating wounds are inconvenient on account of the air entering by the aperture in such a quantity as to prevent the expansion of the lungs, a small wound will be eligible, especially as air does not require a large one for its escape. Mr. Hewson recommends dissecting cautiously with a knife, in preference to the coarse and hazardous method of thrusting in a trocar.

There is one error in Hewson's paper, for which he has been justly criticised by John Bell; viz., the idea that it is possible and proper to make the collapsed lung expand by making an opening in the chest. Bromfield and B. Bell imbibed the same erroneous opinion, and proposed plans for exhausting the air and expanding the lung. It is certain that it is impracticable to make the collapsed viscus expand, until the breach of it is closed, and this closure is greatly promoted by the quiet state in which the collapsed lung remains; a state, also, the most favourable for the stoppage of any bleeding from the pulmonary vessels.

The true object then of making an opening in the thorax, when the symptoms of suffocation are violent, is not to obtain an expansion of the lung on the affected side, nor to take the pressure of the air from it, but to remove the pressure caused on the opposite lung by the distension of the mediastinum, and, at the same time, to diminish the pressure of the air on the diaphragm. The lung on the affected side must continue collapsed, and it is most advantageous that it should do so. The opposite lung is that, which for a time must of itself carry on respiration, and it is known to be fully adequate to the function, provided the quantity of air, on the other side of the chest, does not produce too much pressure on the mediastinum and diaphragm.

Mr. John Bell concludes his remarks on this subject, with advising the following practice:—

1st. When the crackling tumour begins to form over a fractured rib, small punctures should be made with the point of a lancet, as in bleeding; and if the point be struck deep enough, the air will rush out audibly. But, as (supposing the lung is not adherent to the inside of the chest) this air was in the thorax, before it came into the cellular tissue, it is plain, that the thorax is still full, and that the lung of that side is already collapsed and useless, and must continue so. The purpose, therefore, of making these scarifications, and, espe-

cially, of making them so near the fractured part, is not to relieve the lungs, but merely to prevent the air spreading more widely beneath the skin.

2ndly. If the air should have spread to very remote parts of the body, as to the scrotum, and down the thighs, it will be easier to make small punctures in those parts, to let out the air directly, than to press it along the whole body, till it is brought up to the punctures made on the chest, over the wounded part.

3rdly. If, notwithstanding free punctures and pressing out the air in this way, it is found by the oppression, that either air, or blood, is accumulating within the cavity of the thorax, so as to oppress, not the wounded lung only, which was of course collapsed and useless from the first, but the diaphragm, and through the diaphragm to affect also the sound lung, then a freer incision must be made, through the skin and muscles, and a small puncture should be cautiously made through the pleura, in order to let out the air, or blood, confined in the thorax. (*John Bell, op. cit. p. 278.*)

I believe, with Dupuytren, that making cuts, or punctures in the skin, will be of little service where emphysema is attended with urgent symptoms depending upon the accumulation and confinement of air in internal cavities and organs, though the practice may answer the purpose of preventing the further diffusion of air in the subcutaneous cellular tissue by affording an outlet for it. Hence, if the case be not too far advanced, or joined with complications beyond the reach of surgery, Dupuytren was not adverse to the plan of puncturing the pleura. (*See Clin. Chir. t. i. p. 117.*)

Sometimes the necessity for puncturing the pleura is rendered obvious by the oppressed state of the breathing, and other urgent symptoms of pneumo-thorax; but, from the extreme distension of the integuments it may be, in some rare cases, difficult to ascertain on which side the operation should be performed. In one instance upon record, an incision was made between the sixth and seventh ribs on the left side; every symptom became immediately worse, and death followed in a quarter of an hour. The post mortem examination showed, that the operation had been performed on the wrong side. (*See Halliday, On Emphysema.*) In traumatic cases, or those from fractured rib, I think that such difficulty is not likely to happen; the wound, or fracture, being a guide.

In all these cases, copious and frequently repeated venesection is generally proper; and for the obvious reason, of bringing the quantity of blood in the body into a due relation to the diminished aerating surface.

After a few days, the wound in the collapsed lung is closed by the adhesive inflammation, so that air no longer passes out of it into the cavity of the chest, and the outer wound may therefore be healed. What air is already there is ultimately absorbed, and the lung, expanding in proportion, resumes its original functions.

The application of a bandage round the chest is sometimes practised for the relief of emphysema; and its utility, when the ribs are broken, has been highly spoken of by Mr. Abernethy. "Pressure by bandage (says he) not only hinders the air from diffusing itself through the cellular substance, but serves to prevent it from escaping out of the

wounded lung ; and, of course, facilitates the healing of the wound, which would be prevented by the constant transmission of air. Its early application, therefore, will often prevent a very troublesome symptom, whilst, at the same time, by keeping the fractured bones from motion, it greatly lessens the sufferings of the patient." (*Abernethy's Surgical Works*, vol. ii. p. 179.) When emphysema is complicated with a fractured rib, the latter injury is unquestionably a reason in favour of a bandage. But, whether the pressure of the roller will be useful, or hurtful, with respect to the emphysema itself, or the state of the lungs and respiration, may be questionable. As for its tendency to resist the diffusion of air in the cellular tissue, this circumstance does not appear to me important ; because the air, thus diffused, much as it disfigures the patient, is nearly harmless, at least so long as the pleural cavities, and the interlobular texture of the lungs, remain uninflated ; a danger, also, which no bandaging has any tendency to prevent. Neither will a bandage have so much effect in hindering the diffusion of air, as scarifications, with this important additional consideration, that punctures, or small incisions, made over the broken rib, prevent the spreading of the air, by letting it escape, while a bandage can only do so by more or less resisting its escape from the cavity of the pleura ; which mode of operation in some cases would dangerously interfere with the continuation of respiration by the lung of the opposite side. At the same time, I believe, that when the air extravasated within the injured side of the chest is not in such quantity as to oppress the sound lung, and a rib is broken, a bandage will generally afford great relief. Indeed, it is but justice to Mr. Abernethy to state, that he does not recommend the employment of a bandage in all cases of emphysema. "Patients (says he) will not always be able to wear a bandage, when one lung is collapsed, particularly if any previous disease has existed in the other, as it equally confines the motions of the ribs on both sides, and as every possible enlargement of the chest becomes necessary for the due admission of the air into the lung, which still executes its functions. Under these circumstances, if the emphysema continues (and its continuance must always denote that the wound in the lung is not closed), I should esteem it the best practice to make a small opening into the chest, so that the external air might have a free communication with that cavity ; and then the injured lung must remain motionless till its wound is healed, and the mediastinum will, in every state of the thorax, preserve its natural situation." (*Abernethy*, vol. cit. p. 183.) In the case recorded by Cheston, the patient on having a compress and bandage applied, exclaimed that he could not endure it.

When emphysema was combined with a fractured rib, and not any urgent compression of the lungs by air in the cavity of the pleura, Dupuytren used to bleed, apply to the injured side compresses wetted with a resolvent lotion, and then surround the chest with a bandage, so as to suspend the action of the external muscles of respiration, and oblige the patient to breathe entirely by the diaphragm, the principle insisted upon by Abernethy. In this manner the union of the fracture was promoted, and, as was believed, the causes of emphysema opposed. The possibility of a person

breathing wholly by the diaphragm seemed proved to Dupuytren by what happens in injuries of the upper part of the spinal chord, when all the external muscles are struck with paralysis. (*Clin. Chir.* t. i. p. 115.) When, however, the respiration was dangerously interrupted by the accumulation of air in the pleura, Dupuytren abstained from applying a bandage, which he conceived to be only likely to augment the patient's sufferings. (See *Clin. Chir.* t. i. p. 117.)

The utility of a free incision, and scarifications, is well illustrated in a case recorded by Larrey. The emphysema arose from a wound of the lungs by a lance. The whole body was prodigiously swelled ; the integuments so distended that the limbs were inflexible, the eyes buried ; and the lips so enlarged that nothing could be introduced into the mouth. The pulse and respiration were scarcely perceptible, and the voice feeble and interrupted. The lance had entered obliquely under the lower angle of the scapula ; and though the external and internal orifices of the wound were not parallel, the surgeon had applied adhesive straps, and closed the external one. Hence the air, as it escaped from the lungs, distended the cellular tissue. Larrey immediately removed the dressings ; and, with a bistoury, made the openings in the pleura and skin parallel. Cupping glasses were then applied over the wound, and quickly filled with air and blood. The lips of the wound were now brought together, and kept so with a suitable bandage. Cupping glasses and scarificators were applied to various parts of the body, and, in others, incisions were made with a scalpel. The patient recovered. (See *Mém. de Chir. Militaire*, t. iv.)

In emphysema, dependent upon over distension and rupture of the air cells, and the escape of air into the interlobular tissue of the lungs, and thence through the mediastinum, into the common cellular tissue, the best practice is that of diminishing the violence of the respiratory efforts, by which the air is forced at each respiration into the mediastinum. With this view, copious venesection should be employed, for the double purpose of relieving the pulmonary congestion, and of diminishing the mass of circulating fluid ; for, by lessening the quantity of blood for oxygenation, we also lessen the necessity for taking in so large a supply of air for the purpose, and, in the same proportion, diminish the efforts made by the muscles of respiration to dilate and contract the thorax. Opiates should be employed with the same intent ; and the antiphlogistic regimen enforced. (See *Townsend in Cyclop. of Prac. Medicine*, art. Emphysema ; and *Laennec, On Dis. of the Chest*, ed. by Forbes.)

Emphysema has been known to arise from the bursting of a vomica, and ulceration of the surface of the lungs ; but the air which escapes cannot pass into the cavity of the thorax, because the inflammation which precedes the abscess and ulceration of the air-cells closes those which are adjacent, and produces an adhesion of the edges of the vomica, or ulcer, to the inner surface of the chest, so as entirely to separate the two cavities. Palfyn and Dr. Hunter met with cases, in which emphysema originated from abscesses of the lungs, attended with adhesion to the pleura and ulcerations in the situation of such adhesion. In these instances, the pus having made its way through

the pleura and intercostal muscles, the air escaped through the same track, and passed into the cellular tissue on the outside of the chest.

A violent effort of respiration has sometimes produced a certain degree of emphysema, which first makes its appearance about the clavicles, and afterwards spreads over the neck and adjacent parts. The efforts of labour have been known to occasion it. (*Medical Communications*, vol. i. p. 176; *Blackden, in Med. Facts and Experiments*, vol. ii.; *Wilmer's Obs. in Surgery*, p. 143; and *Halliday on Emphysema*.)

Dr. Johnson, of Dublin, met with six examples of this in his practice. In general, the emphysematous swelling is confined to the neighbourhood of the throat, where it first makes its appearance; but it may spread to a vast extent, and even to the very tips of the fingers. In whooping cough emphysema may be produced, as proved by the observations of Drs. Johnson, Mackintosh, and Beattie. (See *Cyclop. of Pract. Med.* art. *Emphysema*.) I agree with the writer of this article in thinking it highly probable that many cases of emphysema supposed to be spontaneous, really proceed from a rupture of the air-cells of the lungs. Thus, besides the emphysema, which sometimes appears on the sides of the thorax, when much force is employed to reduce a dislocation of the humerus, which was believed by Desault to depend upon a rupture of the air-cells, caused by the violent efforts which the patient makes to hold his breath during the reduction of the dislocation, the emphysematous swellings, which are noticed occasionally in hysteria, may admit of similar explanation, the air being forced through the cellular tissue of the lung and mediastinum by the violent efforts at expiration made during the paroxysm, while the glottis is spasmodically constricted. (*Townsend, ib.*)

Louis described an emphysema, which, on account of its cause, and the indication furnished by it to the practitioner, is highly important. It took place in a young girl, who died suffocated from a bean falling into her windpipe; and he considers it, though not correctly, as a pathognomonic symptom of such an accident, concerning the existence of which it is so essential not to commit any mistake. (See *TRACHEOTOMY*.) It made its appearance on both sides of the neck, above the clavicles, and came on suddenly, on the third day after the accident. The inspection of the body proved, that the lungs and mediastinum were also in an emphysematous state. The retention of the air, confined by the foreign body, produced, says Louis, at each attempt to expire, and, especially, when the violent fits of coughing occurred, a strong propulsion of this fluid towards the surface of the lung, into the spongy surface of this viscus. Thence, the air passed into the cellular texture, which unites the surface of the lung to the pleura pulmonalis; and, by communications from cells to cells, it caused a prodigious swelling of the cellular tissue, between the two layers of the mediastinum. The emphysema, increasing, at length made its appearance above the clavicles. This tumefaction of the lung, and surrounding parts, in consequence of the air getting into their spongy and cellular texture, is an evident cause of suffocation, and the swelling seems so natural an effect of the presence of a foreign body in the trachea, that one can hardly fail to think it an essential symptom, though no

author has made mention of it. (*Mém. de l'Acad. de Chir.* t. iv. in 4to.) The emphysematous swelling, sometimes formed in the axilla, in the reduction of a dislocated shoulder was accounted for by Desault and Bichat, on the same principle as the foregoing case, viz. a rupture of one of the air-cells, by the patient's efforts to hold his breath during the reduction of the bone.

The example, lately recorded by Dr. Ireland, as one of idiopathic emphysema following pneumonia, bears so strong a resemblance to the case above cited from M. Louis, that I cannot refrain from suspecting, that it may have been one of the same nature. (See *Trans. of the King's and Queen's College of Physicians*, vol. iii. art. 4.)

An emphysematous swelling of the head, neck, and chest, has also been noticed in typhoid fevers. Dr. Huxham relates an instance of this sort, in a sailor of a scorbutic habit. (*Medical Obs. and Inquiries*, vol. iii. art. 4.) Another example in a case of bilious fever is on record. (See *London Med. Repository*, No. 73.) A case of spontaneous emphysema is likewise described by Dr. Baillie. (See *Trans. for the Improvement of Med. and Chir. Knowledge*, vol. i. p. 202.)

A curious example of what has been called a spontaneous emphysema, is reported by Mr. Allan Burns:—"The patient was a strong athletic man, who, about six years previous to his application at the Royal Infirmary, had received a smart blow on the neck from the keel of a boat. This injury was soon followed by the formation of a firm tense tumour, on the place which had been hurt. The swelling increased very slowly, during the five years immediately succeeding its commencement; but, during the sixth, it received a very rapid addition to its bulk. At this time, it measured nearly six inches in diameter, seemed to be confined by a firm and dense covering, and the morbid parts had an obscure fluctuation. From the first to the last, the tumour had been productive of very little pain.

"Judging from the apparent fluctuation that the tumour was encysted, it was resolved, at a consultation, to puncture the swelling, draw off its contents, and then pass a seton through it. By plunging a lancet into it, only a very small quantity of blood, partly coagulated, and partly fluid, was discharged; a quantity so trifling, that, after its evacuation, the size of the tumour was not perceptibly reduced. A seton was passed through the swelling. At this time the man was in perfect health.

"About ten hours after the operation, the patient was seized with extremely violent rigors, followed by heat, thirst, pain in the back, excessive pain in the tumour, and oppressive sickness.

"An emetic was prescribed; but instead of producing vomiting, it operated as a cathartic. To remove the irritation, the seton was withdrawn. The pain in the tumour, however, and the general uneasiness continued to increase, and thirty hours subsequent to making the puncture, air began to issue from the track of the seton; and afterwards the cellular membrane of the neck, and of the other parts of the body in succession, became distended with a gaseous fluid. In the course of a few hours, after the commencement of the general emphysema, the man died.

"Twelve hours after death, when the body was free from putrefaction, it was inspected. The em-

physema was neither increased nor diminished since death; and some idea may be formed of its extent, when the scrotum was distended to the size of the head of an adult. Even the cavities of the heart, and the canals of the blood-vessels, contained a considerable quantity of air. We could discover no direct communication between the tumour and the trachea or lungs, although such was carefully sought for." (*A. Burns on the Surgical Anatomy of the Head and Neck*, pp. 51—53.)

From such cases, we may infer, that from the mere rupture of a few of the bronchial cells, occasioned by irregular action of the lungs, or by some other internal cause, a spontaneous diffusion of air may take place in the cellular tissue. Such examples are dependent on the same cause as emphysema from injury of the lungs; only the rupture of the bronchial cells in the former cases is less obvious.

Emphysema frequently attends gangrene, especially the humid. Here, however, the air is the product of putrefaction, and the disorder has not the smallest connection with any injury, or disease, of the lungs. In one instance of gangrene from an external cause, Dr. Hunter found, that he could as easily mark the progress of the mortification from day to day by the emphysema, as by the change of colour in the integuments. (See *Med. Obs. and Inq.* vol. ii.) Gangrene, when accompanied by emphysema, is observed to have a great disposition to spread. (See *James on Inflammation*, p. 96.)

A remarkable case is recorded by Dr. Duncan, in which several emphysematous tumours were formed in succession over the chest and neck, in consequence of communications formed by ulceration between the lung and common cellular tissue. (See *Edinb. Med. Chir. Trans.* vol. i.) Or the air may first get into the cavity of the pleura, so as to occasion pneumo-thorax, and afterwards pass into the cellular tissue through an ulceration of the pleura costalis. (See *Halliday*, *Op. cit.*) Emphysema has been known to arise from the passage of air from the alimentary canal, through a rupture of its parietes. (*Haller, Opuscula Pathol. Obs.* 31, t. iii.) A violent contusion of the abdomen has produced in this way an extensive emphysema. (See *Archives Gén. de Méd.*) In ruminating animals, in consequence of the fermentation of their food, the accident is not uncommon. (See *Obs. sur les Animaux Domestiques*, par MM. Chabert et Huzard.)

EMPLASTRUM. [Plasters are adhesive applications intended to cover for a considerable period the part to which they are applied. They are usually spread on linen or leather. Some plasters, as the emplastrum plumbi, the emplastrum saponis, the emplastrum resinæ, can hardly be said to possess any medicinal properties; they are principally used for their adhesive and protective qualities, either to bring the edges of recent wounds together, and retain them in position, or simply to cover tender surfaces. They are also used to maintain uniform pressure, especially in the treatment of varicose ulcers, for which latter purpose they are applied in strips from the ankle to the knee. (See **ULCERS**.) Mr. Liston introduced a simple unirritating adhesive plaster for adjusting recent wounds, composed of isinglass and gin, which, when spread on white silk, is sufficiently transparent to admit of the edges of the wound being seen from day to day without disturbing the plaster.

Other plasters possess stimulating anodyne or specific properties. Of these, the emplastrum ammoniaci, the emplastrum picis, the emplastrum galbani, are of the first kind; the emplastrum opii, the emplastrum belladonnæ, of the second; and the emplastrum hydrargyri, and the emplastrum potassii iodidi, of the third. The ordinary blistering plaster, or emp. lyttæ, may be considered as simply irritating without possessing any other medicinal quality; while the emplastrum ammoniaci c. hydrargyro possesses stimulating and specific properties combined. For the exact composition of the several plasters used in practice the reader is referred to the *London Pharmacopœia*. In the treatment of chronic affections of the larger joints great advantages have been derived from the methodical application of plasters, as practised and recommended by the late Mr. Scott of Bromley, by the means of which, warmth, a moderate degree of pressure, counter-irritant, and specific agents, were all brought to render at one and the same time unremittingly their combined remedial effects in counteracting the tedious joint disease.]

EMPYEMA (from ἐν, within, and πύον, pus, or matter). A collection of purulent matter in the cavity of the chest.

The ancients made use of the word "empyema" to express every kind of internal suppuration. It was *Ætius* who first restricted the term to collections of pus in the cavity of the pleura, or membrane lining the chest; and all the best modern surgeons invariably attach this meaning alone to the expression.

The operation for empyema—thoracentesis—properly means the making of an opening into the thorax, for the purpose of discharging pus collected in the cavity of the pleura, though the phrase with several writers denotes making an incision into the chest, in order to let out any effused or confined fluid, whether matter, blood, or a serous fluid. It is not always easy, however, to determine, *à priori*, the precise nature of the fluid collected in the chest. Thus, in a case of empyema of two months' standing, occasioned by the bursting of a tubercular abscess of the lung into the pleura, the fluid was observed by Dr. Townsend to present all the characters of genuine pus; while, in another case, where the effusion was produced by a similar cause, and assumed the same chronic form, thoracentesis gave issue to a fluid as transparent and colourless

as water. (See *Cyclop. of Pract. Med.* art. *Empyema*.)

Acute and chronic abscesses not unfrequently form in the cellular tissue, between the pleura and the ribs, and intercostal muscles. A swelling occurs between two of those bones; the skin does not undergo any change of colour; a fluctuation is distinguishable, and sometimes extensive œdema.

With respect to abscesses formed in the cellular tissue, connecting the pleura costalis to the intercostal muscles, they rarely burst into the chest, because the pleura is in such case considerably thickened. However, in order to keep them from spreading extensively, as well as to obviate any possibility of their breaking inwards, the best rule is to make an early, and, if possible, a depending opening into them. The motions of respiration then both promote the exit of the matter, as well as the contraction of the cavity in which it was lodged; and the disease, if unattended with caries, generally terminates favourably.

It often happens, however, that the abscess is caused by a carious rib, and then the cure is more tedious and difficult. A modern writer, indeed, informs us that, when the inside of the rib is extensively carious, or when the caries is near the junction of the bone to the spine, the fistula is incurable. (*Lassus, Pathologie Chir.* t. i. p. 128, edit. 1809.) On the other hand, another surgeon of vast experience recommends us to endeavour to separate the diseased bone, either by cutting it away or employing the trepan. (*Pelletan, Clinique Chir.* t. iii. p. 253.) Were a part of a diseased rib to admit of being sawn away, Mr. Hey's convex saw would be a more proper instrument for the purpose than a trepan.

An abscess of the preceding kind may be so situated, and attended with such a pulsation, as greatly to resemble an aneurism of the origin of the aorta. An interesting case of this description is detailed by Pelletan (*Clinique Chir.* t. iii. p. 254), and another was seen by Boyer. (*Mal. Chir.* t. vii. p. 333.)

When the surface of the lungs, and that of the pleura costalis have become adherent to each other, around the abscess, so as to constitute what is termed *encysted empyema*, the pus, disposed by a law of nature to make its way to the surface of the body, generally occasions ulceration of the intercostal muscles, and collects on the outside of them. An abscess of this kind comes on with a deep-seated pain in the part affected; an œdematous swelling, which retains the impression of the finger; and a fluctuation, which is at first not very distinct, but, from day to day, becomes more and more palpable, and, at length, leads the surgeon to make an opening.

If this be not done when the fluctuation becomes perceptible, the abscess may possibly insinuate itself into the cavity of the pleura, in consequence of the adhesion being in part destroyed by ulceration. Sabatier affirms that the case may take this course, even when the abscess has been punctured, and while a free external opening exists; and this experienced surgeon has adduced a fact in confirmation of such an occurrence. (See *Méd. Opératoire*, tom. ii. p. 249.)

In a few instances, the surface of the lung ulcerates, and the matter is voided from the trachea. If inflammation occurs in the anterior mediastinum, and ends in suppuration, the abscess may possibly

burst into neither of the cavities of the chest, but make its way outwards, after rendering the sternum carious, as happened in the example recorded by Van Swieten. (*Comment on Boerhaave's 895th Aphorism.*)

But though collections of matter in the anterior mediastinum are influenced by the general law, in accordance with which abscesses tend to the surface of the body, and though it be true that they rarely burst into the cavity of the pleura, the contrary may happen, as is proved by the 9th case in La Martinière's memoir, on the operation of trepanning the sternum. Here the event was the more unexpected, as there was already an external opening in the abscess.

External injuries, such as the perforation of the sternum with a sword (*Vanderwiel, Obs.* 29, Cent. 1), a contusion, a fracture, or a caries of this bone, may give rise to an abscess in the anterior mediastinum. Galen has recorded a memorable example, where the abscess was the consequence of a wound of the fore part of the chest. After the injury, which was in the region of the sternum, seemed quite well, an abscess formed in the same situation, and being opened, healed up. The part, however, soon inflamed, and suppurated again. The abscess could not now be cured. A consultation was held, at which Galen attended. As the sternum was obviously carious, and the pulsation of the heart was visible, every one was afraid of undertaking the treatment of the case, since it was conceived that it would be necessary to open the thorax itself. Galen, however, engaged to manage the treatment without making any such opening, and he expressed his opinion that he should be able to effect a cure. After the removal of a portion of the bone, the heart was quite exposed (as is alleged), by reason of the pericardium having been destroyed by the previous disease. The patient experienced a speedy recovery.

J. L. Petit met with an abscess in the anterior mediastinum, in consequence of a gun-shot wound in the situation of the sternum. The injury had been merely dressed with some digestive application; no dilatation, nor any particular examination of the wound had been made. The patient, being to all appearance quite well, joined his regiment again, but was soon taken ill with irregular shiverings, and other febrile symptoms. Petit probed the wound, and found the bone affected. As there was a difficulty of breathing, he suspected an abscess either in the diploe or behind the sternum, and, consequently, he proposed laying the bone bare, and applying a trepan. The operation afforded an outlet for some sanious matter, and, as soon as the inner part of the sternum had been perforated, a quantity of pus was discharged. The patient was relieved, and afterwards recovered. (*Petit, Mal. Chir.* t. i. p. 80.)

Another instance, in which an abscess behind the sternum was cured by making a perforation in that bone, opposite the lower part of the cavity, in which the matter had collected, is recorded by De la Martinière. (*Mém. de l'Acad. de Chir.* t. xii. edit. 12mo.)

When, in consequence of inflammation, an abscess forms deeply in the substance of the lungs, the pus more easily makes its way into the air-cells, and tends towards the bronchi than towards the surface of the lungs. In this case the patient spits up purulent matter. When the opening, by which

the abscess has burst internally, is large, and the pus escapes from it in considerable quantity at a time, the patient is in some danger of being suffocated. However, if the opening be not immoderately large, and the pus, which is effused, be not too copious, a recovery may ensue. Collections of matter in the liver may also be discharged by the pus being coughed up through the trachea, when the parts affected become connected with the lungs by adhesions, and the abscesses of the liver are situated on its convex surface. When the collection of matter in the liver takes place on its concave surface, the pus sometimes makes its way into the colon, and is discharged with the stools. Several cases of this kind are related by authors: Sabatier has recorded two (*Méd. Opératoire*); Le Dran makes mention of others; and Pemberton (*Diseases of the Abdominal Viscera*, p. 36) relates additional instances of a similar nature.

I shall now proceed to the consideration of empyema, strictly so called. Sometimes it is a consequence of a penetrating wound of the chest; occasionally it proceeds from the bursting of one or more vomicae; in a few examples, it arises from the particular way in which abscesses of the liver burst (*Journ. de Méd.* t. iii. p. 47. *Morgagni*, epist. xxx. art. 4); but, in the greater number of instances, originates from pleuritic inflammation, either acute or chronic. (*Boyer, Mal. Chir.* t. vii. p. 352.) Empyema more rarely takes place in both than in one cavity of the pleura.

Sometimes firm adhesions intersect the purulent effusion, and divide the sac of the pleura into distinct compartments. Dr. Townsend examined the body of a patient, who died of empyema in the Whitworth Hospital, and in whom the effusion was contained in three compartments, so perfectly distinct from each other, that, if paracentesis had been performed, only one of the three separate collections would have been discharged. (See *Cyclop. of Pract. Medicine*, art. *Empyema*.) In all cases the purulent, or thinner fluid of empyema may be said to be principally, if not entirely, a morbid secretion from the pleura; and even where pus or other matter is introduced from another source, as from the rupture of a pulmonary or hepatic abscess, the collection of fluid, which constitutes the empyema consequent thereon, does not consist so much of the matter of the abscess, as of the morbid secretion from the pleura, which the irritation caused by the presence of that matter produces. (*Townsend*, ib.)

In cases of empyema, the pleura is almost constantly lined with a coating of adventitious matter, which gives the interior of the chest much more the appearance of the walls of a large abscess, than of a cavity lined with a serous membrane. The membrane is susceptible of inflammation, ulceration, and gangrene, and when the latter change occurs, the detachment of the slough may form an outlet for the empyema. The adventitious membrane of serous tissues is also capable of undergoing fibrous, cartilaginous, and calcareous transformations, and is liable to the development of tubercles in it. These are generally small and numerous, and mostly follow chronic pleuritis. Sometimes, however, they form numerously and rapidly. (See *Andrat, Clinique Méd.* t. ii.)

When empyema arises from thoracic inflammation, pleuritis, or pneumonia, the symptoms characterising it are usually preceded by those of

the disease, of which the effusion of pus into the pleura is the effect. Inquiry must, therefore, be made whether the patient has had pleurisy, or peripneumony, the symptoms of which have lasted longer than a fortnight: and whether, after a transient amendment, there have been frequent shiverings, followed by a low continued fever, with nightly exacerbations. Now these first circumstances justify the belief, that the inflammatory disorder has terminated in suppuration, and that the symptoms afterwards experienced depend upon effusion of matter into the chest. Some of these symptoms arise from the mechanical action of the pus upon the lungs, heart, and parietes of the chest, and belong also to other effusions in the thorax; the rest may be said to be the effects of ulceration and suppuration of the parts on the animal economy, and, therefore, particularly belong to empyema.

First, of the common symptoms, the respiration is difficult, short, and frequent; the patient suffers great oppression, and experiences a sense of suffocation, and of weight upon the diaphragm. He cannot move about, even for a short time, without being quite out of breath, and threatened with syncope. He has an almost incessant, and very fatiguing cough, which is sometimes dry, sometimes attended with expectoration. (*Boyer, Mal. Chir.* t. vii. p. 356.)

Few writers of the last century have described the symptoms of empyema with more discrimination and accuracy than Mr. Samuel Sharp. He remarks, that it has been almost universally taught, that, when a fluid is extravasated in the thorax, the patient can only lie on the diseased side, the weight of the incumbent fluid on the mediastinum becoming troublesome, if he places himself on the sound side. For the same reason, when there is fluid in both cavities of the thorax, the patient finds it most easy to lie on his back, or to lean forwards, in order that the fluid may neither press upon the mediastinum, nor the diaphragm. But it is noticed by Mr. Sharp, that, however true this doctrine may prove in most instances, there are a few, in which, notwithstanding the extravasation, the patient does not complain of more inconvenience in one posture than another, nor even of any great difficulty of breathing. (See *Le Dran's Obs.* 217; and *Marchetti*, 65.)

On this account, observes Mr. Sharp, it is sometimes less easy to determine when the operation is requisite, than if we had so exact a criterion as we are generally supposed to have. But, says he, though this may be wanting, there are some other circumstances, which will generally guide us with a reasonable certainty. He states, that the most infallible symptom of a large quantity of fluid in one of the cavities of the thorax, is a preternatural expansion of that side of the chest where it lies; for, in proportion as the fluid accumulates, it will necessarily elevate the ribs on that side, and prevent them from contracting so much in expiration as the ribs on the other side. This change is said to be most evident when the surgeon views the back of the chest. (*Boyer*, vol. cit. p. 357.) Mr. Sharp also refers to *Le Dran's Obs.* 211, vol. i., in order to prove, that the pressure of the fluid on the lungs may sometimes be so great, as to make them collapse, and almost totally obstruct their function. When, therefore, says Mr. Sharp, the thorax becomes thus expanded, after a previous pulmonary

disorder, and the case is attended with the symptoms of suppuration, it is probably owing to a collection of matter. The patient, he observes, will also labour under a continual low fever, and a particular anxiety from the load of fluid.

Besides this dilatation of the cavity by an accumulation of the fluid, the patient will be sensible of an undulation, which is sometimes so evident that a bystander can plainly hear it in certain motions of the body. Mr. Sharp adds, that this was the case with a patient of his own, on whom he performed the operation: but the fluid, in this instance, he says, was very thin, being a serous liquid, rather than pus. Sometimes, when the practitioner applies his ear close to the patient's chest, while this is agitated, a noise can be heard, like that produced by shaking a small cask not quite full of water. (See *Dr. Archer's Case, in Trans. of the Fellows, &c. of the King's and Queen's College of Physicians in Ireland*, vol. ii. p. 2.) In this instance, the fluid resembled whey. [Such undulations of the fluid, however, are only to be thus recognised, when air, as well as fluid, is present in the pleural cavity.]

According to the same author, it will also frequently happen, that though the skin and intercostal muscles are not inflamed, they will become œdematous in certain parts of the thorax; or, if they are not œdematous, they will be a little thickened; or, as Boyer states, the intercostal spaces are widened, and, when the empyema is considerable, instead of being depressed, as they are in thin persons, they project beyond the level of the ribs. (*Mal. Chir.* t. vii. p. 357.) These symptoms, joined with the enlargement of the thorax, and the preceding affection of the pleura or lungs, seem unquestionably to indicate the propriety of the operation. But, observes Mr. Sharp, amongst other motives to recommend it upon such an emergency, this is one, that if the operator should mistake the case, an incision of the intercostal muscles would neither be very painful, nor dangerous. (See *Critical Inquiry into the present State of Surgery*, sect. on EMPYEMA.)

"The difficulty of lying on the side, opposite to the collection of pus," says Le Dran, "is always accounted a sign of an empyema. This sign, indeed, is in the affirmative; but, the want of it does not prove the negative; because, when there is adhesion of the lungs to the mediastinum, the patient may lie equally on both sides." (*Le Dran's Obs.* p. 103, edit. 2.) The explanation of this circumstance, offered by Le Dran, is, that when the cyst, in which the matter is contained, is between the mediastinum and the lungs, the mediastinum gradually yields to the volume of the pus, in proportion as it is formed, and the cyst in which it is contained becomes dilated; "whence habitude becomes a second nature." Whereas, in an empyemal person, in whom the lung is not adherent to the mediastinum, and who lies on the side opposite to that on which the collection of pus is situated, the mediastinum is on a sudden loaded with an unusual weight of fluid. (P. 111.)

Richerand contends, that the difficulty of breathing, which patients with extravasated fluid in the chest experience in lying upon the side opposite to that on which the disease is situated, never originates, as has been commonly taught and believed, from the fluid pressing upon the mediastinum and opposite lung. "I have (says

he) produced artificial cases of hydrothorax, by injecting water into the thorax of several dead subjects, through a wound made in the side. This experiment can only be made on subjects in which the lungs are not adherent to the parietes of the chest. In this way from three to four pints of water were introduced. I then cautiously opened the opposite side of the chest: the ribs and lungs being removed, the mediastinum could be distinctly seen, reaching from the vertebræ to the sternum, and supporting, without yielding, the weight of the liquid, in whatever position the body was placed.

"It is evident, then, that patients, with thoracic extravasations, lie on the diseased side, in order not to obstruct the dilatation of the sound side of the respiratory organs, one part of which is already in a state of inaction. It is for the same reason, and in order not to increase the pain by the tension of the inflamed pleura, that pleuritic patients lie on the diseased side. The same thing is observable in peripneumony: in a word, in all affections of the parietes of the chest." (*Nosogr. Chir.* t. iv. pp. 168, 169, edit. 2.)

There may be some truth in the foregoing statement; but the experiments are far from being conclusive, with respect to the assertion that, in empyema, hydrothorax, &c. the fluid on one side of the chest does not compress the opposite lung. In the first place, the quantity of fluid is frequently much larger than that which Richerand injected. Secondly, although the mediastinum may not be apt to yield at once to the weight of a liquid suddenly injected into one side of the thorax; yet it frequently does so by the gradual effect of disease. Thirdly, many of the phenomena of empyema seem adverse to Richerand's inference.

In opposition to Richerand's view, Dr. Townsend argues, that we have direct proof of the influence of the weight of the fluid; for, in pneumo-thorax with empyema, the patient can generally lie on the sound side, so long as the effusion is principally gaseous; but, as the proportion of ponderable fluid increases, decubitus on the sound side becomes impossible. In like manner, in cases of empyema, the dyspnoea is generally greatly aggravated by this posture; but, when the fluid has been discharged, the patient is immediately able to lie on the sound side, though the necessity for its free dilation continues as great as ever, the diseased side being still in a state of inaction. Thus, in a case of empyema with pneumo-thorax, where paracentesis was performed, the patient could lie on the sound side on the night after the fluid was drawn off, though it was ascertained by auscultation that the side was then filled with air. (See *Dublin Hospital Reports*, vol. v.; and *Townsend in Cyclopædia of Practical Medicine*, art. *Empyema*.)

[In empyema with pneumo-thorax, the distension of the pleural cavity with air often occasions pressure through the mediastinum upon the healthy lung. (See EMPHYSEMA.) The proof that fluid in one pleura may compress the opposite lung is given in the fact, stated below, that the heart may be thereby pushed towards the healthy side of the chest.]

When empyema is double, the patient can seldom lie in the horizontal position; but remains seated, and with the trunk inclined forward.

Although surgeons should be aware that pa-

tients with empyema can sometimes lie in any position, without particular aggravation of the difficulty of breathing, yet, it ought to be distinctly understood, that the generality of patients cannot place themselves on the side opposite to that on which the collection of pus is situated, without their respiration being very materially obstructed. Another circumstance, also, which deserves to be mentioned while we are treating of the symptoms of empyema, is, that the œdema of the integuments is sometimes not confined to the thorax, but extends to more remote parts, on the same side of the body as the collection of matter. Both the foregoing remarks are confirmed by an interesting case published by Mr. Hey.

Sept. 3, 1788, Mr. Hey was desired to visit John Wilkinson, who had been ill ten days of the influenza. The patient was found labouring under a fever, attended with cough, difficulty of breathing, and pain in the left side of the thorax. He was bled once; blisters were repeatedly applied to the chest; and he took nitre and antimonials, with a smooth linctus to allay his cough. "He was repeatedly relieved by these means, especially by the application of the blisters; but repeatedly relapsed. At last, he became so ill, that he breathed with the utmost difficulty, and could not lie on the right side, without danger of immediate suffocation."

Mr. Hey found the patient in the state just now described on the 17th of September. "His face and especially his eyelids were a little swollen on the left side." The left side of the thorax was larger than the right, and its integuments were œdematous. Upon pressing the intercostal muscles, they felt distended; they yielded a little to a strong pressure, but rebounded again. The abdomen, especially at its upper part, appeared to be fuller than in the natural state. (See *Hey's Practical Obs. in Surgery*, p. 476.) This last symptom is also particularly noticed by Boyer. (*Mal. Chir.* t. vii. p. 357.)

Another remarkable symptom, which is occasionally produced by collections of fluids in the chest, is an alteration in the position of the heart. I have seen a patient in St. Bartholomew's hospital, who had so large a quantity of matter in the left bag of the pleura, that it completely displaced the heart, which pulsated against the inside of the chest, at a considerable distance to the right of the sternum. This man's life might perhaps have been saved, had paracentesis thoracis been performed in time. Some suspected an aneurism from the throbbing on the right of the sternum; and the case was not fully understood till after death, when the body was opened. Closer attention to the symptom, however, might have shown that it was an empyema, and that making an opening, for the discharge of the matter, afforded the only rational chance of preserving life. There had been pain and inflammation in the chest, followed by shiverings; there was very great difficulty of breathing; the heart, which previously used to beat in the usual place, no longer did so; but now pulsated on the right side of the thorax.

That the heart should be displaced in this manner by any large collection of fluid in the left cavity of the thorax, one would naturally expect. Baron Larrey has related a highly-interesting case, where the heart was not only pushed considerably to the right of the sternum, but its action was so much impeded by the derangement of its position,

that the pulse in the large arteries was thereby rendered extremely feeble. In this instance, also, the diaphragm had descended so low down as to force some of the small intestines into the cavity of the pelvis. (*Mém. de Chir. Militaire*, t. iii. p. 447, &c.) Pelletan has recorded an example, in which a collection of fluid in the left cavity of the chest displaced the heart, the pulsations of which were perceptible betwixt the third and fourth ribs of the right side, near the sternum. (*Clinique Chir.* t. iii. p. 276.) Boyer speaks of one case, in which the displacement of the heart was so extensive that its pulsations were felt near the right axilla. (*Traité des Mal. Chir.* t. vii. p. 357.) In the anatomical collection at Strasburg, is a preparation exhibiting the displacement of the heart into the right side of the chest, by matter in the left pleura, the left lung being nearly annihilated. (*Lobstein, Compte de son Muséum Anat.* p. 39, 8vo. 1820.) When empyema is on the right side, the change in the heart's position is not in general so remarkable; yet, with the stethoscope, it will generally be found to pulsate considerably to the left of its natural situation. In two cases, referred to by Dr. Townsend, the pulsation was distinctly felt in the axilla between the fourth and fifth ribs. (*Cyclopædia of Pract. Med.* art. *Empyema*.) The heart is sometimes thrust downward by collections of fluid in both sides of the chest, and its pulsation is distinguishable in the epigastrium. (*Hodgson, On the Diseases of Arteries and Veins*, p. 95.) In cases of extensive empyema, even the liver has been pressed down into the right iliac fossa. (*Stoll, Ratio Medendi*.) The descent of the diaphragm, by thrusting the abdominal viscera before it, may cause an appearance as if the liver were enlarged. Of this, an instance is recorded by M. Roux, the true nature of which was detected by Bichat, who cured the patient by paracentesis. (*Œuvr. Chir. de Desault*, t. iii.)

When the cavity of the pleura contains fluid, and the surgeon strikes the thorax repeatedly with the ends of his fingers, a dull sound is produced, quite different from what would occur, were the chest in its natural state. Besides this dulness of sound on percussion, the respiratory murmur is absent on the diseased side, which remains perfectly motionless, when the cavity is entirely filled with fluid. Sometimes the lung is not completely compressed by the fluid, and then a diminished respiratory murmur, œgophony, &c., may be heard over parts of the thorax. In the opposite lung, puerile respiration is distinguishable, accompanied with violent action of the respiratory muscles.

The symptoms of empyema are frequently equivocal. Panarolius opened a man, whose left lung was destroyed, at the same time that the thorax contained a considerable quantity of pus. Although the patient had been ill for two months, he had suffered no difficulty of breathing, and had had only a slight cough. Le Dran met with a case of nearly the same kind. A patient, who had been for three days affected with a considerable oppression, and an acute pain on the left side of the chest, got somewhat better. He felt no material difficulty of breathing, on whatever side he lay. The only thing which he complained of, was the sense of a fluctuation in the thorax, and a little obstruction of his respiration, when he was in a sitting posture. These symptoms did not seem sufficiently decided

to justify the operation, and it was delayed. The febrile symptoms continued, with cold sweats, and the patient died on the eighth day. Five pints of pus were found collected in the chest. (See *Le Dran's Obs. in Surgery*, pp. 109, 110, edit. 2.)

The symptoms more particularly depending upon empyema itself, that is to say, upon disease and suppuration within the chest, are nearly the same as those which accompany all large deep-seated abscesses. The fever attending the thoracic inflammation, which ends in suppuration, gradually diminishes, but does not entirely cease. On the contrary, it soon changes into hectic, attended with flushings of the cheeks, heat of the palm of the hands, and exacerbations every evening, and after meals. In the night, the upper parts of the body are covered with perspiration; the patient is tormented with insatiable thirst; his appetite fails; his debility becomes extreme; he is subject to frequent fainting fits; diarrhoea ensues; and the finger nails become curved, shining, and of the yellow tinge observable all over the body. At length, the utmost emaciation, and the facies Hippocratica, come on, frequently attended with dilated pupils, and enfeebled vision, and indicating the approach of death.

As the operation of empyema, and some other particulars, relating to this subject, are treated of in another part of this Dictionary (see PARACENTESIS OF THE THORAX), it will only be necessary for me here to subjoin a list of works, which may be advantageously consulted for information on empyema.

ENCANTHIS (from ἐν, and κἀνθος, the angle of the eye), at its commencement, is a small, soft, red, and sometimes rather livid, excrescence, which grows from the caruncula lachrymalis, and, at the same time, from the neighbouring semilunar fold of the conjunctiva. The inveterate encanthis is ordinarily of considerable magnitude; its roots extend beyond the caruncula lachrymalis and semilunar fold, to the membranous lining of one or both eyelids. The patient experiences very serious inconvenience from its interposition between the commissure of the eyelids, which it necessarily keeps asunder.

Thus, indeed, it keeps up a chronic ophthalmia, impedes the action of the eyelids, and, in particular, prevents the complete closure of the eye. Besides, partly by compressing, and partly by displacing the orifices of the puncta lachrymalia, it obstructs the free passage of the tears into the nose.

According to Scarpa, this excrescence, on its first appearance, is commonly granulated, like a mulberry, or is of a ragged and fringed structure. Afterwards, when it has acquired a certain size, one part of it represents a granulated tumour, while the rest appears like a smooth, whitish, or ash-coloured substance, streaked with varicose vessels, sometimes advancing as far over the conjunctiva, covering the side of the eye next to the nose, as where the cornea and sclerotic unite. In this advanced state, the encanthis constantly interests the caruncula lachrymalis, the plica semilunaris, and the membranous lining of one or both eyelids. In addition to the roots, which in such circumstances connect the excrescence with the caruncula lachrymalis, the semilunar fold, and the conjunctiva of the globe of the eye, the encanthis emits an appendage, or prominent firm elongation, along the inside of the upper or lower eyelid, in the direction of its edge. The middle, or body, of the encanthis divides near the cornea, as it were, like a swallow's tail, to form two appendages, or elongations, one of which extends along the inner surface of the upper eyelid by the margin of which it is covered, while the other shoots in a direction from the internal towards the external angle, along the inside of the lower eyelid, which also conceals it beneath its edge.

The body of the encanthis, or that middle portion of the whole excrescence, which reaches from the caruncula lachrymalis and semilunar fold, inclusively, over the conjunctiva almost to the junction of the sclerotica with the cornea, sometimes forms a prominence, as large as a small nut or chestnut. At other times, it is of considerable size, but depressed, and broken down, as it were, at its centre. Still, however, the body of the encanthis preserves that granulated appearance which prevailed at first; while one, or both the appendages, on the inside of the eyelids, appear rather like a fleshy than a granulated substance.

Sometimes, the encanthis assumes a cancerous malignancy, evinced by the dull, red, leaden, or (as Beer says) the bluish-red colour of the excrescence; by its excessive hardness, and the lancinating pains which occur in it, and extend to the forehead, the whole eye-ball, and the temple, especially when the tumour has been slightly touched; by the propensity of the excrescence to bleed; and by the partial ulcerations on its surface, which emit a fungous substance, and a thin, and exceedingly acrid discharge. The disease is constantly attended with epiphora, and preceded by a scirrhus induration of the caruncle. The eyeball, and neighbouring bones, which are of a spongy texture, soon participate in the disease, and the lower eyelid becomes everted. (*Beer*, *Lehre von den Augenkr.* b. ii. p. 187, 188.) This form of encanthis only admits of palliative treatment; unless, indeed, an effort be made to extirpate it entirely, together with the whole of what is contained in the orbit, and, even then, the event is dubious.

Beer joins Scarpa in the statement that the operation rarely proves successful, and adds, that it is always followed by an incurable weeping, and

a considerable eversion of the lower eyelid. (Vol. cit. p. 189.) Fortunately, the truly cancerous encanthis is uncommon; Mr. Guthrie has not seen it; (*Operative Surgery of the Eye*, p. 117), and Mr. Travers, who was surgeon to the London Eye Infirmary several years, never met with an instance of it. (*Synopsis of Diseases of the Eye*, p. 103.)

The benign encanthis, how large soever it may be, is always curable by extirpation. Those instances, which are small, incipient, and granulated, like a mulberry, or of a fringed structure, which originate either from the caruncula lachrymalis, or the semilunar fold of the conjunctiva, or from both these parts together, and even in part from the internal commissure of the eyelids, may be raised by means of a pair of hook forceps, and cut off from the whole of their origin, closely to their base, with the curved scissors with convex edges. In cutting out an encanthis of small size, care should be taken not to remove, together with that portion of the excrescence which originates from the caruncula lachrymalis, any more of this latter body than is absolutely necessary for the precise eradication of the disease, in order that no irremediable weeping may be occasioned.

When the little excrescence has been detached from all its roots, says Scarpa, the eye must be washed several times with cold water, in order to cleanse it from the blood, and then it is to be covered with a piece of fine linen, and a retentive bandage. On the 5th, 6th, or 7th day the inflammation arising from the operation entirely ceases, and the suppuration from the wound is accompanied with the mucous appearance already described. The little wounds are then to be touched with a piece of alum, scraped to a point like a crayon, and the zinc collyrium is to be injected into the affected eye several times a day. If these means should not bring about the wished-for cicatrization, but, on the contrary, the small wounds situated on the caruncula and internal commissure of the eyelids should become stationary and covered with proud flesh, the nitrate of silver ought to be applied to them.

Excision is equally applicable to the inveterate encanthis, which is of considerable size, and broken down at its body, or which forms a prominence, as large as a nut, or chestnut, with two fleshy appendages extending along the inner surface of one or both eyelids. The application of a ligature to such an excrescence ought never to be regarded as a method of cure; for the large, inveterate encanthis never has a sufficiently narrow neck to admit of being tied. On the contrary, when the tumour is voluminous, its roots invariably extend to the caruncula lachrymalis, the semilunar fold, and the conjunctiva covering of the eyeball, oftentimes nearly as far as the cornea. In this state, also, the encanthis has one or two fleshy appendages, which reach along the membranous lining of one or both eyelids. Hence, though the ligature were to produce a separation of the body of the encanthis, one or both the appendages would still remain to be extirpated. The second operation could only be accomplished with the knife. In this disease, there is no foundation for the fear of hæmorrhage, to which the advocates for the ligature attach so much importance; for, cases are recorded of considerable, inveterate encanthes being removed, without the least untoward occurrence from loss of blood. To

these, Scarpa observes, he could add a great number of his own, so that no doubt can now be entertained on this point.

When the encanthis is large, and inveterate, with two extensive fleshy elongations, one on the inside of the upper eyelid, and the other on that of the lower one, we are to proceed in the following manner. The patient being seated, an assistant is to turn out the inside of the upper eyelid, so as to make one of the appendages of the encanthis project outward. By means of a small bistoury, a deep incision is next to be made into the elongation, in the direction of the margin of the eyelid; and then having taken hold of, and drawn it forwards with a pair of forceps, we are to separate it, throughout its whole length, from the inside of the upper eyelid, proceeding from the external towards the internal angle of the eye, as far as the body, or middle of the encanthis. We are then to do the same to the lipomatous appendage on the inside of the lower eyelid. Afterwards the body of the encanthis is to be elevated, if possible, with a pair of forceps; but when this instrument will not answer the purpose, a double hook must be employed. This middle portion is now to be detached, partly with the bistoury, and partly with the curved scissors, from the subjacent conjunctiva, on the globe of the eye, from the semilunar fold, and from the caruncula lachrymalis; dividing the substance of this last part more or less deeply, according to the depth and hardness of the large inveterate encanthis. Here it is proper to state distinctly, that when we have to deal with an old, large tumour of this nature, deeply rooted in the caruncula lachrymalis, it is not generally in our power to preserve a sufficient quantity of the substance of this part, to prevent the tears from dropping over the cheek, after the wound is healed.

After the operation the eye is to be repeatedly washed with cold water. The rest of the treatment, consequent to the extirpation of a large encanthis, is almost the same as that explained in speaking of the small incipient case. Bathing the eye very frequently in the lotion of mallows, and employing anodyne, detergent collyria, are the best local means, until the mucous appearance, preceding suppuration, has taken place on the surface of the wound. Then we may have recourse to mild astringent ointments and collyria. The mildest topical applications are generally the best, both in the first stage of suppuration, as well as afterwards, particularly, when, together with the encanthis, a considerable piece of the conjunctiva, covering the eyeball towards the nose, and intimately connected with the body of the excrescence, has been removed.

One enlargement of the lachrymal caruncle admits of cure by the application of leeches, repeated scarifications, and the nitrate of silver. (See *Middlemore, On Diseases of the Eye*, vol. ii. p. 546.)

ENCEPHALOCELE. (From *ἐνκεφαλον*, the brain, and *κήλη*, a tumour.) A hernia of the brain. (See **HERNIA CEREBRI**.)

ENCYSTED TUMOURS. (See **TUMOURS**, **ENCYSTED**.)

ENEMA. The following are some of the most useful glysters employed in the practice of surgery.

Cathartic.

℞. Decocti hordei ℥j.
Sodii chloridi ℥j.—Misce.

℞. Decocti avenæ ℥j.
Olei olivæ ℥ij.
Magnesiæ sulphatis ℥j.—Misce.

Anodyne.

℞. Mucilaginis amyli, Aquæ destillatæ sing.
℥ij. Tincturæ opii guttas XL.—Misce.

℞. Olei olivæ ℥iv. Tincturæ opii guttas XL.—Misce.

The two latter are particularly useful, when great irritation exists about the rectum, bladder, or urethra. They have great effect in diminishing spasmodic affections of this canal and neck of the bladder. Hence they are often employed in retention of urine, in which cases their total quantity should not exceed two or three ounces, which will be more likely than a larger quantity to remain within the bowel a sufficient time to let the anodyne qualities of the opium have the desired influence.

Tobacco,

Employed in cases of strangulated hernia.

℞. Nicotianæ ℥j. Aq. ferventis ℥j. The plant is to be macerated ten minutes, and the liquor then strained for use. One half should be first injected, and soon afterwards the other, unless the glyster operate with dangerous violence, as it sometimes does in particular constitutions.

ENTEROCELE. (From *έντερα*, the bowels, and *κήλη*, a tumour.) A hernia, the contents of which are intestine. (See **HERNIA**.)

ENTERO-EPIPLOCELE. (From *έντερα*, the bowels, *ἐπίπλοον*, the omentum, and *κήλη*, a tumour.) A hernia, the contents of which are both intestine and omentum. (See **HERNIA**.)

ENTROPIUM (from *έν* and *τρεπω*, to turn). An inversion of the eyelids. (See **TRICHLIASIS**.)

EPIPHORA (from *ἐπιφέρω*, to carry with force). By this term is meant an accumulation of tears on the anterior part of the eye; in consequence of which, the person affected is not only under the necessity of frequently wiping them away, but vision is injured by the morbid refraction which they produce of the rays of light that enter the pupil. *Stillicidium lachrymarum* is distinguished by modern writers from epiphora: the cause of stillicidium lies in some obstacle to the absorption and conveyance of the tears from the lacus lacrymarum into the sac. Epiphora, on the other hand, consists in a superabundant secretion of tears, and is a disease of the secreting, not of the excreting, parts of the lachrymal organs. (See *W. M. M'Kenzie's valuable Essay on the Diseases of the Lachrymal Organs*, p. 47. 8vo. Lond. 1819; and *Beer, Lehre von den Augenkr.* b. ii., and art. **LACHRYMAL APPARATUS**.)

EPIPLOCELE. (From *ἐπίπλοον*, the omentum, and *κήλη*, a tumour.) A hernia, formed by a protrusion of the omentum. (See **HERNIA**.)

EPULIS. (From *ἐπι*, upon, and *οὔλα*, the gums.) A small tubercle on the gums. It is

sometimes cancerous. The best plan of cure is to extirpate it with a knife.

ERETHISMUS. (From *ἐρεθίζω*, to irritate.) The state of irritation attending the early stage of acute diseases. Mr. Pearson has described a state of the constitution produced by mercury acting on it as a poison. He calls it the *mercurial erethismus*, and mentions, that it is characterised by great depression of strength, anxiety about the præcordia, irregular action of the heart, frequent sighing, trembling, a small, quick, sometimes intermitting pulse, occasional vomiting, a pale contracted countenance, a sense of coldness: but the tongue is seldom furred, nor are the vital and natural functions much disturbed. In this state, any sudden exertion will sometimes prove fatal. Mr. Pearson advises, with a view of preventing the dangerous tendency of this affection, the immediate discontinuance of the use of mercury; and exposing the patient to a dry cool air. The incipient erethismus may often be averted by the camphor mixture and large doses of ammonia, if mercury be also left off. Sarsaparilla is also beneficial, when the stomach will bear it. (*Pearson, On Lues Venerea*, p. 156, &c. edit. 2.)

ERYSIPELAS is a Greek word, derived, as some say, from *ἐρύειν*, to draw, and *πέλας*, vicinum, because of its tendency to draw neighbouring parts into the same state; in other words, because of its tendency to spread. Others derive it from *ἐρύθρος*, red, and *πέλος*, livid; or from *ἐρύθρος*, and *πέλλα*.

[It may be defined to be a fever, attended with spreading inflammation of the skin, or of the skin and areolar tissue. It begins with shivering, and other symptoms of feverishness; then come a spreading redness and swelling of the skin of the part which is the seat of inflammation. Vesications often follow; and the disease, in its milder form, may produce no worse effects than loss of cuticle, and shedding of the hair. In severe cases, widely spread unhealthy exudation into the areolar tissue ensues, with sloughing.

Much confusion has arisen from the use of the term *erythema*; which has been applied to designate sometimes the mildest forms of erysipelas, sometimes mere redness of the skin from local causes. Cullen, for instance, said, "When the external inflammation is an exanthema, and symptomatic of an affection of the whole system, I shall then name the disease **ERYSIPELAS**; but when the disease is an affection of the skin alone, and very little of the whole system, or when the affection of the system is only symptomatic of the external inflammation, I shall give the disease the name of **ERYTHEMA**." (*Cullen's First Lines*, vol. i. p. 296.) Yet Cullen really describes what is generally known as simple erysipelas under the term *erythema*.

The fact is, that under the word **ERYTHEMA** (whose consequence in nosology would soon vanish if it were replaced by its English equivalent, **REDNESS**), are confounded many affections which have no alliance with erysipelas, nor with each other. For instance, there is the *erythema nodosum*, a peculiar exudation into the areolar tissue of the shins and elbows, whose real alliance is with purpura; and the *erythema intertrigo*, or chafing of infants when not kept clean; and there are the varieties caused by sunburn, and by frost bite, and by rube-facient and irritating applications. The better plan will be to exclude absolutely from erysipelas all

erythematous affections arising from local causes, or from slight derangements of the stomach, and which do not possess the spreading character, and true alliances and tendencies of erysipelas.

A consideration of the places in which erysipelas flourishes, of the causes from which it proceeds, and of the maladies to which it may give rise by contagion or infection, shows clearly enough that its alliances are with diffuse inflammation of the areolar tissue, spreading inflammation of veins and lymphatics and of serous and mucous membranes, and puerperal fever—diseases all attended with a poisoned state of the blood, all capable of being produced artificially by contagion or inoculation, and all characterised by the production of exudations, tending to appear at many points, to spread widely, and to diffuse themselves, instead of being concentrated to one focus, like the common phlegmonous inflammation. The term *pyæmia* includes them all.

In this article we shall also treat of the diffuse or erysipelatous inflammation of the areolar tissue, for the reasons just assigned.]

[*History of Opinions.*—Erysipelas has been the subject of many a controversy, in one of which the author of this Dictionary was for some time engaged with Mr. Lawrence. The opinions, too, advanced at different epochs respecting its causes and nature are curious, because they show the gradual advance—sometimes the decay—of medical philosophy. In a surgical dictionary, therefore, some notice must be taken of the views held from time to time by the fathers of our profession. Referring to the article INFLAMMATION for a fuller account, we may here give a few brief notices only.

Hippocrates evidently considered the disease epidemic and constitutional. He gives the following history: "Early in spring, along with the prevailing cold, there were many cases of erysipelas. They were of a malignant nature, and proved fatal to many; many had sore throat, and loss of speech." "In many cases erysipelas, from some obvious cause, such as an accident, and sometimes from even a very small wound, broke out all over the body; especially about the head in persons advanced in life, if such an accident were neglected in the slightest degree, and this happened in some who were under treatment; great inflammation took place, and the erysipelas quickly spread all over. In most of them, the abscesses ended in suppurations, and there were great sloughings of the flesh, tendons, and bones, and the defluxion which seated in the part was not like pus, but a sort of putrefaction, and the running was large and of various characters." (*Works Syd. Soc.* vol. i. p. 401. *Epidemics*, book iii.)

Galen defines erysipelas as redness, with burning inflammation, often with fever and shiverings; or a red painful swelling, arising from bilious blood. It has swelling and heat like phlegmon; but whereas phlegmon is red, erysipelas is paler, and yellow. It does not throb like phlegmon. But when a sanguineous afflux is mixed with the bilious, the erysipelas is phlegmonoid. The doctrine of Galen was, that afflux of blood produced phlegmon, of bile erysipelas and herpetic affections; of phlegm, œdema; and of black bile or melancholy, schirrus; and these doctrines, sound in themselves, with certain modifications, were repeated by almost all writers down to the time of Hunter and Cullen.

The opinions held by the most part of English

practitioners, during the first half of the eighteenth century, may be gathered from the works of Dr. Daniel Turner, who says: "The erysipelas, by which we understand the same with the St. Anthony's fire, may be defined a preternatural affection of the skin, taking rise from a bilious effervescence of the blood, throwing forth those particles which are no longer fit to be assimilated, to the surface of the skin; there producing a small tumour and tension upon the part, accompanied with fever, heat, pricking pain, with a redness inclined to yellow, which presently recedes upon a gentle impression of the finger, and as quickly returns after the same is removed."

To quote Ambrose Paré, Wiseman, or any of the other surgical writers of the sixteenth, seventeenth, and first half of the eighteenth centuries, would be to reproduce the ideas, and almost the words, of Galen. Thus Wiseman says, that the erysipelas is generated of a hot bilious serum in the blood, and that there is no erysipelas that hath not a fever, visible or latent, going before it.

Sydenham, the father of English rational medicine, describes the disease as erysipelatous fever. He says that it may attack any part of the body, at any time of the year, yet that the face is the part most frequently attacked, and the most frequent season the summer. The patient is seized suddenly: his face swells, and is exceedingly red and painful. There is a crop of small pustules, which enlarge and become vesicular, spread along the brow and head, and close the eyes through their puffiness. Whatever the part of the body, and whatever the time of year, there is generally the combination of chills and shivers; unless, indeed, they precede the inflammation, which they sometimes do by two or three days. "I consider," he says, "that in this disease peccant matter is mixed with the blood, and that it must be evacuated. Also that the ebullition of the blood must be regulated by cooling remedies; also that matter which has become impacted in the parts must be discussed and eliminated." (*Works by Syd. Soc.* on *Intercurrent Fevers*, vol. i. p. 260.) Sydenham wrote what he had seen and not what he had read.]

John Hunter says: "The erysipelatous inflammation is very peculiar, and most inflammations that are not of the true adhesive and suppurative kind are called so, although probably they do not in the least belong to it; and this may arise more from the want of terms than the want of discrimination. This inflammation often arises spontaneously, or in consequence of a low or debilitating fever. It often arises from accident, but then it is commonly a secondary inflammation, though not always, for the first shall have gone off, and when suppuration was about to take place it shall have come kindly on, but afterwards the erysipelatous shall take place." "It is more commonly a cutaneous inflammation than situated in the deeper seated parts, although in some constitutions every inflammation, wherever it exists, will most probably be of this kind; however, the skin appears to be most susceptible of it, because it will spread over a prodigious surface of skin, while it does not affect even the cellular membrane underneath, at least not commonly. There is an inflammation which attacks internal canals, which is classed with the erysipelatous, but how far it is the same I do not know." "It is more common to the throat than any other part, often going down the trachea

Whatever it is, it may be considered in some of its effects to be in direct opposition to the adhesive and the suppurative inflammations ; for where the adhesive most readily produces adhesions, there the erysipelatous does not, as in the common cellular membrane ; and where the adhesive seldom takes place, excepting from extreme violence, then this inflammation, if erysipelatous, has a tendency to produce adhesions, as in canals or outlets." "Whatever the inflammation may be, it is certainly attended with nearly the same kind of constitutional affection. The fever in both appears to be the same ; viz. accompanied with debility, languor, &c. The extravasation, in consequence of the erysipelatous inflammation, is not so great as in either the adhesive or the cedematous, nor is it of that kind which produces adhesions between the parts inflamed, which in this inflammation would commonly be unnecessary, as it seldom produces suppuration, but is attended with very bad consequences when it does. It appears to support itself by continued sympathy, for it commonly begins at a point and spreads, while it shall be getting well where it first began." Hunter says, in a note : "But the inflammation may be such as to contaminate while it spreads." (*Hunter, On the Blood*, Palmer's ed., vol. iii. p. 314, part ii. ch. ii. sect. 70.)

[Cullen "supposed the erysipelas to depend on a matter generated in the body, and which, analogous to the other cases of exanthemata, is in consequence of fever thrown out upon the surface of the body. I own it may be difficult to apply this to every particular case of erysipelas ; but I take the case in which it is generally supposed to apply—that of erysipelas of the face." "The disease is not commonly contagious, but as it may arise from an acrid matter externally applied, so it is possible that the disease may be sometimes communicated from one person to another. Persons who have once laboured under this disease are liable to returns of it." (*First Lines*, loc. cit.)

It will be seen, as we more fully show in art. INFLAMMATION, that Hunter's philosophy is a pure *solidism*, based upon the supposition of peculiar modes of action of the living parts, and not upon the notion of a change of composition. He treats of inflammation, and of each variety of it, as a specific action, or mode of action, working in the parts concerned, with results influenced partly by the kind of action, partly by the structure of the parts and their powers.

The abuse of this doctrine, and neglect of the ancient humoralism, led to the extravagant notions of inflammation as a process of increased action and power, which are not extinct even in our own day.]

Dr. Carmichael Smith, for example, contended that erysipelas was an inflammation of the skin, and that all its phenomena and peculiarities arise entirely from the structure involved.

Mr. Lawrence, at one time, was supposed to advocate most strongly the doctrine of the *simple inflammatory* or *phlegmonic*, in contradistinction to the *specific* nature of erysipelas. He observes, that "a consideration of the origin, development, and effects of erysipelas, whether local or general, leads us irresistibly to the conclusion, that the nature of the affection is inflammatory. In its four leading characters of redness, swelling, heat, and pain, and in its effects of effusion, suppuration, and sloughing, it agrees with what is called common or phlegmonous inflammation ; while the general disturbance,

preceding and accompanying the local affection, is often exactly alike in the two cases. Erysipelas then is merely a particular modification of cutaneous, or cutaneous and cellular inflammation. If we were to class these according to their natural affinities, we should place erysipelas between the exanthemata and phlegmon. It is less diffused than the former, not so circumscribed as the latter. The exanthemata are confined to the skin ; erysipelas affects both skin and cellular structure ; while phlegmon has its original seat in the latter, the skin being secondarily involved."

Yet he continues : "The difference between erysipelas and phlegmon, however, is not merely in the original seat, or degree of the disturbance : there is also a difference in kind. We may indeed say, generally, that phlegmon is a more violent inflammation than erysipelas, but sloughing of the cellular substance is more frequent in the latter than the former. The most striking and important distinction between the two affections is, that inflammation is confined to one spot in phlegmon, and is distinctly circumscribed in its seat, while it is diffused in erysipelas, and spreads without limit. This difference seems to depend on the adhesive character of the inflammatory process in the former ; the substance called coagulating, coagulable, or organisable lymph, effused around the inflamed part, forms a boundary between it and the sound portion, which is altogether wanting in erysipelas. In the latter, the effusion is serous ; hence, when matter is formed, it is not confined to one spot, but becomes extensively diffused in the cellular tissue." (*Med. Chir. Trans.* vol. xiv. p. 17., &c.)

[Mr. Nunneley, whose most able monograph on erysipelas is the standard work on the subject, treats of it as a type and example of a class of affections which ought to be separated in idea from true phlegmonous inflammation. He speaks of two local and constitutional conditions respectively ; to one of which he gives—after Mr. Travers—the name irritation and irritative fever ; to the other, inflammation. "These two conditions of constitution are, when clearly exhibited, widely different from each other, and may be regarded as the two extremes of a scale between which there is every conceivable grade. In the one case, we shall have much vascular excitement, with corresponding power in the nervous energy, and if the disturbance be occasioned by an external injury, there will be a great tendency to limit the mischief by the effusion of coagulable lymph ;" "or if the disturbance depend upon some more general cause, and the action be exhibited upon one of the continuous membranes, it is also marked by the effusion of plastic lymph, which is capable of becoming organised." "In the opposite condition, whether the effect be from external injury, or constitutional cause, there is no such effort made to limit the action by the effusion of plastic lymph ; on the contrary, there is considerable tendency for the mischief to spread extensively, and if lymph be effused it is not of the organisable kind," "and is accompanied by much serum." "There is great vascular excitement without corresponding nervous energy ; hence the pulse is always very quick, seldom full or hard, but often jerking and easily compressed." To the former of these conditions the epithet *phlegmonoid diathesis*, to the latter *erysipelatoid diathesis* may be applied.

Further, it is Mr. Nunneley's opinion, that these two diatheses may be exhibited pure, or in every degree of intermixture, "as the limited adhesive type prevails it will be phlegmonoid, as the diffuse unadhesive type, erysipeloid." (Nunneley, *On Erysipelas*. Lond. 1841.)

It will be evident from this *catena* of opinions, that erysipelas, as a specific inflammation of the skin, has been known from the earliest times; and not only so, but that it has been taken as a type or specimen of a particular sort of inflammation, to which the name erysipelatos was given. Further, it has always been taken for a constitutional, and not for a mere local malady; it is treated as a *fever*, with local accidents; and of the conditions giving rise to it, all opinion down to the antiphlogistic school of Cullen and Hunter pointed to *bile*, that is, to an impure state of blood caused by disorder of the digestive organs.]

[*Divisions*.—The divisions of erysipelas have been numberless, according to its severity, and the depth of tissues involved, and other attendant circumstances. Thus there is the *erysipelas simplex*, *vel superficiale*, *vel cutaneum*, the redness moderate, of a yellow colour; swelling slight. *Erysipelas œdematosum*, whose name declares its character. *E. phlegmonoides*, attended with great exudation into the subcutaneous tissue, and tending to wide suppuration. *E. biliosum*, *erraticum*, *gangrenosum*, and others, whose names require no commentary.

Fenger, in his elaborate Thesis (*De Erysipelate Ambulanti*, Havniæ, 1853) endeavours to establish a marked distinction between erysipelas *ambulans* and erysipelas *vulgaris*; the former he believes to be a true exanthema, the latter simple inflammation of the skin; the former has a distinct raised margin, the characteristic of specific eruptions; the fever severe, the mortality one in eight, the duration at least eleven days; the eruption tends to be symmetrical and marches regularly, just as a liquid does when imbibed by blotting-paper. The erysipelas *vulgaris*, on the contrary, has but an ephemeral fever; the mortality one per cent.; half the cases convalesce on the fourth day; the edge of the inflamed part diffused, and gradually lost; and that it does not march regularly. Hence that the erysipelas *ambulans* is a specific exanthema; the erysipelas *vulgaris* mere common inflammation of a patch of skin. Our own opinion is, that this division is arbitrary; and like all divisions founded on *degree*, is essentially unphilosophical. How many species of scarlet fever would there be, if the cases were classified on the like basis? It must be borne in mind, that diseases, as described in books, are *ideas* or *abstractions*, not separate entities limited by matter; and that it is impossible to select any cases to be included under any given name, of many of which it may not fairly be doubted whether they are fairly included or not. There are slight cases of erysipelas, as of typhoid, scarlatina, and the like, of which the nature is to be decided by *analogy more than by physical proof*. There seems no absolute line of demarcation between erysipelas, and unhealthy or low diffused inflammation of skin.

For our purposes it will suffice if we treat of the subject under the heads of (1) the simple or cutaneous; (2) the phlegmonous, or cellulocutaneous of Nunneley; and (3) the subcutaneous erysipelas, or diffuse inflammation of the areolar tissue.

Symptoms.—Simple or cutaneous erysipelas generally attacks the face and scalp, particularly

if idiopathic. We may accordingly select this as a typical case for description.

For a variable number of days, the patient complains of general indisposition, loss of appetite, weakness, and dejection; violent headache, sometimes well marked sour and bilious vomiting, and shiverings of greater or less violence. Some degree of redness, puffiness, and tenderness is then usually noticed on the nose, or low down on the forehead. Sleep is excessively disturbed by dreams, or broken, or altogether lost, or is mixed with a considerable amount of delirium. Soon the swelling extends over the whole face and scalp. The skin is puffed and shining, its colour varying from the palest to the most vivid redness, or again to a dusky purple, or to a decided yellowish cast. The redness disappears immediately on pressure with the finger, and as speedily returns when the pressure is discontinued. It is circumscribed by a line usually irregular. The swelling may be very slight, yet still so that some difference is felt by the finger in passing from the sound to the inflamed parts. Again, the swelling may be very considerable on the third or fourth day, from œdematous exudation into the areolar tissue, so as to close the eyelids, and render the features indistinguishable. Some of the lymphatics at the back of the neck may be enlarged and inflamed. The heat felt is often very great, and accompanied with vivid arterial redness; but in this and other symptoms denoting sthenic intensity, there may be the greatest differences. The heat in an œdematous swelling may be scarcely above the natural. The patient feels a severe stinging, itching, smarting sensation, with intense tenderness to the touch. The whole skin is hot and dry, the pulse is frequent, the tongue white or yellowish and dirty, and the other signs of fever are present, especially headache and delirium.

Then comes the event. In one case, after the face and scalp shall have been involved,—rarely in less than five or seven days (that is, about the tenth from the commencement),—the nightly headache and the fever abate, the pulse becomes slower, and the skin cool, the swelling gradually subsides, and the only vestige of the malady is a reddened or purplish colour, with exfoliation of the cuticle in branny scales, and usually a falling off of the hair. The cases in which this favourable termination by *resolution* is most likely to occur, are those in which biliary disorder has preceded the attack, and has been treated by an effective course of purgatives.

In a second case (and, in fact, in the majority), *vesications* occur, particularly about the eyelids. Serous effusion takes place from the inflamed surface, elevating the cuticle into smaller or larger vesicles, or into bullæ like those produced by blisters; or raising it by a soft, yellow, jelly-like deposit, which remains slightly adherent to both the cutis and cuticle. The contents of the vesicles or bullæ are transparent, sometimes nearly colourless, but more commonly yellowish; sometimes they consist of a thin pus; or they may exhibit a bloody or livid discolouration. The fluid loses its clearness, becoming thicker, opaque, and whitish, or yellowish. The cuticle gives way; the fluid escapes, and incrustations form, which soon fall off, leaving the skin sound; or they may lead to superficial ulcerations. It is not often that bullæ form except on the face.

In a third case, towards the decline of the disease, there may be an increase of pain, at one or more particular spots, and abscesses may form under the skin.

Fourthly, the disease, instead of disappearing cleanly, may take on the *wandering character*. As it declines on the face it spreads down the back of the neck, and over the throat, and even down the arms and legs, disappearing on one side as it spreads on the other. The redness in such cases is usually dusky; the swelling and heat slight; the patient feeble; the cause either long-continued chronic disorder of the assimilating organs, or long confinement in foul air, or any equivalent cause of a thorough break-down of the health; and the result, in aged persons, often death from exhaustion. Mr. Nunneley quotes a case in which it lasted seven weeks.

Thus, we commonly see the various stages of erysipelas existing together at the same time in different parts of the skin; the portion last affected is red and swelled; another part is vesicated; while others exhibit incrustation and desquamation. Sometimes it leaves the part first affected to appear in a distant situation. Its origin, development, and complete termination, seldom take place in one and the same spot.

Fifthly, the malady may be complicated with congestion or effusion within the skull; marked firstly by delirium, afterwards by insensibility, and far more frequently with signs of debility, low pulse, brown or black dry tongue, teeth covered with sordes, and not accompanied with any signs of vigorous inflammation.

Lastly, a precisely similar train of symptoms attends simple erysipelas when taking its starting-point from a wound, and beginning in any other part besides the head.]

An uncommon variety of this disease is an *universal erysipelas*. No disorder is more subject than the present to relapses; but a remarkable thing, sometimes attending the return of the complaint, is its being sometimes strictly *periodical*. In chlorotic women, the erysipelatous attack is occasionally made every month just at the period when the menses should take place. (*Hoffman*.) This periodical nature of erysipelas has been observed in men: Larrey knew two male patients, one of whom used to be attacked with erysipelas twice a year at the time of the equinox; the other had only one attack annually, which was wont to happen in the beginning of the spring. My friend Mr. Maul, of Southampton, once informed me of an erysipelas, which was both periodical and universal, affecting a lady several times at intervals of two years.

In the phlegmonous, or cellulocutaneous erysipelas, termed by Dupuytren *diffuse phlegmon*, (*Clin. Chir.* t. ii. p. 289), the skin is more raised than in the simple form of the complaint, the swelling is harder and deeper, and of a darker colour. The redness has often a brownish or dark livid tint; and the discolouration is sometimes irregular, giving to the part a marbled appearance. The whole depth of the adipous and cellular textures may be loaded with effusion, so that the arm or leg appears of twice the natural size. The sensation of heat and pain is aggravated in a very severe degree, and may be accompanied with throbbing. The swollen part at first yields slightly to the pressure of the finger, but sub-

sequently becomes tense and firm. Vesications, often minute and miliary, form on the surface, with purulent contents; but sloughing of the cellular tissue soon comes on, and the febrile symptoms are aggravated. According to Mr. Lawrence's observations, these dangers are not attended with increased swelling, elevation, and pointing, as in phlegmon; on the contrary, there is rather a diminution of tension, a subsidence, and a feel of softness in the part. A similar account is given by Dupuytren, who states that, when the disorder has reached the period when phlyctenæ have formed, and the cellular tissue becomes thickened and indurated, the symptoms appear for two, three or four days to be stationary; and an inexperienced surgeon is even led to hope for the resolution of the inflammation, while the danger is really urgent, and suppuration already exists. (*See Clin. Chir.* t. ii. p. 311.) Experience alone can teach the practitioner to distrust this deceitful stage, and not to neglect timely incisions. In fact, as Dupuytren observes, in two or three days, if the disease be allowed to make progress, the skin separates from the subjacent parts, and breaks, or the phlyctenæ give way; a dark-coloured serosity flows out; and white, or sometimes black sloughs are visible under the skin, which extend with rapidity. (*Clin. Chir.* t. ii. p. 312.) At first the cellular texture contains a whey-like or whitish serum. The fluid gradually becomes yellow and purulent, and we often find it presenting all the characters of good pus, and very thick. The serum is diffused through the cells at an early period, and a mixture of serum and pus often fills a considerable portion of the cellular texture, without any distinct boundary. Frequently matter is deposited in small separate portions, forming a kind of little abscesses, which often run irregularly in the cellular texture. This texture turns gray, yellowish or tawny, and sometimes appears like a dirty spongy substance filled with a turbid fluid: thus losing its vitality altogether, it is converted into more or less considerable fibrous shreds, of various size and figure, which come away soaked with matter like a sponge. The integuments over a large slough of this kind, being deprived of their vascular supply, become livid, and often lose their vitality. The suppurating and sloughing processes go on to a great extent when an entire limb is affected, sometimes completely detaching the skin, and often separating it through a large space; occasionally penetrating deeper, passing between the muscles, causing inflammation of them, suppuration between them, and often sloughing of the tendons. When the substance of a limb is thus generally inflamed, the joints do not escape; inflammation of the synovial membranes, effusion of matter into the joint, and ulceration of the cartilages take place. (*See Hutchinson's Practical Obs.* p. 115. ed. 2; and *Bibl. Med.* Sept. 1827, p. 331.) Dupuytren refers to cases, in which a quart of matter was discharged daily, and to one fatal instance in the Hôtel Dieu, where the whole leg was stripped of the skin and cellular tissue, and the tibia and patella denuded. (*See Clin. Chir.* t. ii. p. 314.) If, however, the patient should recover after tedious suppurations and discharge of sloughs, the parts which have been inflamed, are so changed in structure, and skin, fascia, muscles, tendons, and bones, are so mate-

rially agglutinated and fixed, after the extensive destruction of the connecting cellular texture, that the motions of the part are permanently and seriously injured. (See *Lawrence, in Med. Chir. Trans.* vol. xiv. p. 12.)

The integuments of an entire limb, from the trochanter to the ankle, may form huge bags of matter, and be almost entirely detached from the fascia beneath. Nay, there may be suppuration underneath the fascia.

In the body, and especially in the legs, the skin often mortifies to a large extent, owing to the cutting off of the small nerves and nutrient blood-vessels which supply it. [Hence, says Mr. Nunneley, the propriety of the caution on which Dupuytren so particularly insists, of using the utmost care in dressing an erysipelatous leg, that we do not destroy the small bands which may yet connect the skin with the subjacent parts, lest we should still further deprive it of vitality by cutting off the only remaining means of nutrition. This consecutive gangrene is rarely seen in the scalp, where, nevertheless, this form of erysipelas is frequent. The distribution of the arteries and nerves is very different in the scalp from that of the limbs; in it they are placed between the skin and the occipito-frontal aponeurosis. The temporal, frontal, and occipital arteries are so connected to the integuments, that in dissection it is very difficult to separate them. Now, as the suppuration takes place beneath the aponeurosis, the skin is not deprived of its supply of blood or nervous energy, and consequently maintains its vitality, even though the whole of the cellular tissue between the pericranium and aponeurosis be destroyed, as does sometimes happen. (*Nunneley, op. cit.* p. 169.)]

The attack of phlegmonous erysipelas, and especially of the spontaneous form of it, is announced by a greater or less degree of shivering, which is followed by heat, and febrile disturbance. The fever, though of the continued type, has paroxysms and remissions, two or three times a day. A slight uneasiness in the skin is often felt twenty-four or thirty-six hours before the shivering takes place. The skin afterwards assumes a rose colour, which is not uniform, but has a winding appearance; and in this stage, whether the case is to be simple or phlegmonous erysipelas would be difficult to prognosticate, were it not for a degree of œdema in the subcutaneous cellular texture, and the *pitting* caused by the pressure of the finger. Afterwards the symptoms increase, the fever is redoubled, and the finger, strongly pressed upon the skin, no longer makes an impression or hollow in it; but, on the contrary, feels a considerable resistance; the redness, which is intense, assumes a darker, or even a purplish colour; the skin becomes shining; phlyctenæ arise; the cellular tissue is dense and indurated; the urinous and other secretions are diminished, altered, or suppressed; and the patient is in a constipated, sleepless, and extremely agitated state. (See *Dupuytren in Clin. Chir.* t. ii. p. 310.)

[*Diagnosis.*—Erysipelas is not likely to be confounded with scarlatina, roseola, or any other of the exanthemata, which, instead of being confined to one part, or wandering slowly, appear almost universally diffused, or rapidly pass over the entire surface. So also, between erysipelas

and phlegmonous inflammation, in most cases there is no ground for mistake. In phlegmon, says Mr. Nunneley, the inflammation is well circumscribed and well defined by a boundary of lymph; the swelling is at first much harder, stands out more in relief, and appears more considerable than in erysipelas; suppuration takes place in the middle, which points conically where the skin becomes thin and fluctuates. The colour is lighter, more vivid, does not disappear on pressure, as in erysipelas; the pain is of the acute throbbing kind. There is not the tendency to the formation of vesications. Inflammation and suppuration under a fascia will, of course, neither possess the redness and œdema of erysipelas, nor the *pointing* of phlegmon.

Erysipelatous or *diffuse inflammation of the areolar tissue*; *subcutaneous erysipelas* of Nunneley; *cellular erysipelas*, or *diffuse abscess*, may be defined a fever, accompanied with diffuse inflammation of the areolar tissue. It is almost the same as phlegmonous erysipelas without the inflammation of the surface of the skin; and in most of the cases recorded, it shows a greater alliance to intense pyæmia than even phlegmonous erysipelas usually does; inasmuch as it is more frequently attended with suppurations at various parts of the body; and inasmuch as death more frequently occurs from blood-poisoning, or from visceral disease, than is the case in cutaneous erysipelas. Substitute a poisoned wound for the act of parturition, in an unhealthy atmosphere, and this disease is the homologue of puerperal fever.

It has attracted considerable notice from the fact that it is frequently produced by wounds received in dissection, and that many members of our profession have fallen victims to it. Amongst the earliest and best descriptions of it, are those of Dr. Duncan, *Edinburgh Med. Chir. Trans.*, vol. i.; Dr. Colles, *Dublin Hospital Reports*, vol. iii. 1822; James, of Exeter, *On Inflammation, &c.*; Dr. Copland, author of the immortal *Medical Dictionary*; Mr. Travers, *Enquiry on Constitutional Irritation*; Mr. Adam, *Glasgow Med. Journal*, 1830; and Mr. Stafford, *Med. Chir. Trans.*, vol. xx. 1836. But above all these there is the admirable monograph on *Irritative Fever, or the Plymouth Dock-yard Disease*, 1825, by Dr. John Butter, of Plymouth, which well deserves to be read, not merely for its accuracy as a relation of facts, and its sound therapeutical doctrine, but because the epidemic which it records is so extraordinary and so complete an illustration of the alliance of erysipelas, diffuse inflammation, and pyæmia. The following abstract of the Plymouth disease will be important to the end of time.

Case 1. On August 1st, 1824, a shipwright laid up by a punctured wound in the sole of the foot; on the 7th considerable fever came on, and inflammation extended up the leg; headache, nausea, and thirst. 9th. Whole limb enlarged and erysipelatous. 12th. Extending up thigh. 14th. To the abdomen. 15th. Death. No post-mortem. *Treatment.* Bleeding to syncope twice; repeated purges.

Case 2. On 4th August, 1824, a carpenter wounded right hand by a saw. 6th. Considerable fever; hand inflamed. 10th. Whole arm erysipelatous; abscess opened on back of hand, which on 12th freely discharged pus and sloughs. 13th and 15th. Incisions made in forearm and arm; improvement to the 26th, when hand and forearm nearly

sound, but a sudden pain in left thigh, which is œdematous. Sept. 15th. Immense abscess opened in thigh. 25th. Sloughing. October 2nd. Gangrene of heel; death. *Treatment.* At first, bleeding to 34 oz., and purging; then incisions, bark, and opium.

Case 3. 16th August, 1824, a shipwright, æt. 45, suffered amputation of last joint of left fore finger, from an accident. 20th. Pain in hand and headache. 21st. Stump *easy and looking inactive.* 24th. Great prostration, anxiety, and nausea. 25th. Death. *Post-mortem.* Sixteen oz. serum in chest; right lung adherent; left gangrenous; intestines inflamed; abscess round right kidney. *Treatment.* Bleeding to 24 oz. on the 20th, and a cruel quantity of calomel and cathartics afterwards.

Case 4. A joiner tore the nail of his finger on 10th August, 1824. On the 18th finger healthily granulating; but a sudden attack of rigors and fever. 20th. Increased fever and headache; hand and arm much inflamed. 25th. Whole hand and arm erysipelatous and œdematous; great exhaustion; an incision into the back of the hand; areolar tissue found infected with pus; from this, recovery is dated. *Treatment.* Bleeding to 34 oz.; leeches, calomel, and cathartics, and the incision.

Case 5. A sawyer, on 30th August, tore off nail of left great toe. Sept. 1st. Pain and shivering. 2nd. Great fever. 4th. Erysipelas of whole limb. 9th. Sphacelus over external ankle; incisions gave vent to sloughs like wash leather. Death on 14th. *Treatment.* Twenty-four leeches to the foot; three bleedings altogether to 60 oz.; calomel and cathartics, and incisions.

Case 6. A shipwright, on 7th, 8th, and 9th Sept. received sundry small abrasions of left shin. 13th. Shivering; pains in inguinal glands; red lines. 15th. Fever, pain, and swelling of thigh increased. 18th. Pain in right hypochondrium. 19th. Death. *Post-mortem.* Inflammation and seropurulent effusion into abdomen. *Treatment.* Bleedings to 54 oz.; leeches and purges.

Case 7. A shipwright wounded his chin with a nail on 18th Sept. On 17th. Shivering and headache. 18th. Neck much swollen. 22nd. Erysipelas advancing over face and head. 25th. Large vesicles. 26th. Amendment began; and convalescence complete in eleven weeks. *Treatment.* Leeches, cathartics, poultices, and an incision.

Case 8. A shipwright jammed three fingers on 17th Sept. 1824. 19th. Shivering. 20th. Pain of hand; and an isolated red blush on upper arm. 24th. Whole arm enormously swelled and reddened. 25th. Death. *Treatment.* Bleeding to 40 oz.; repeated leechings; purgatives.

Case 9. Dr. Bell, on the 14th September, 1824, scratched the last phalanx of right fore-finger at the post-mortem of case 6. 19th. Rigors and fever; smarting of scratch, but no other local symptoms. 21st. Restlessness, fever, nausea; great pain and tenderness of right shoulder, none in finger. 22nd. Very prostrate; excruciating pain in back; indistinct vision. 23rd. No pain; tenderness on pectoral muscle when pressed; no redness; finger neither inflamed nor swollen. 24th. Death. *Treatment.* Bleeding twice to 46 oz.; calomel, antimony, purgatives.

Case 10. A shipwright, on 13th September, abraded shin over right inner ankle. 18th. Superficial sloughing and some pain. Oct. 1st. Doing well; but in the evening great pain; red lines to groin; tender glands, shivering and headache. Oct.

2nd. Severe headache. 3rd. *Tenderness of right hypochondrium*; leg *easy.* 4th. Delirium; death. *Post-mortem.* Omentum, ileum, and cæcum, and right lobe of liver inflamed; seropurulent effusion. An incision into the affected leg from the ulcer towards the calf *revealed no traces of inflammation in the cellular substance.* *Treatment.* Bleeding to 76 oz.; sixty leeches; several blisters to head and abdomen; calomel, opium, and cathartics.

Case 11. A labourer, on 9th Oct., grazed the left shin. Nov. 1st. Wound inflamed; pain and fever. 3rd. Erysipelas and inflammation of lymphatics of left leg. 4th. Great tension and agonising pain. Recovery. *Treatment.* An incision, five inches long, down to the fascia, between the tibia and tendo Achillis.

Case 12. A sawyer, on 2nd August, wounded his right great toe. 8th. Pain. 9th. Swelling and inflammation. 10th. Pain. 13th. Gangrene. 15th. Death. *Treatment.* Bleeding and antiphlogistics.

Case 13. A man suffered a compound fracture of right great toe on August 18th, 1824. On the 9th September he resumed his duties in the dockyard, to all appearance well. Sept. 23rd. "Fever arose; a red patch appeared on the outside of his right calf, another on his right thigh, a third on his left arm." Vitiating secretions, delirium, and stupor followed; extensive gangrene of right leg and foot; matter in the cellular membrane which surrounded the extensors of the injured toe. *Treatment.* Bleeding and antiphlogistics.

Case 14. A man bruised his thumb and abraded the shin of his left leg, on 27th August, 1824. He continued at work. On the 8th September, "idiopathic congestive fever" arose, and in two days death followed.

Case 15. A shipwright wounded his hand with glass on 14th September. On the 19th he was attacked with fever, and acute pain in the right armpit and side, with a blush of redness. Death on the 24th, preceded by mortification. *Treatment.* Bleeding to 46 oz.

We have selected this unique collection of cases, in order to show the entire accordance of this "Plymouth Dockyard Disease," *mutatis mutandis*, with an epidemic of puerperal fever. In a dockyard, accidental wounds are of daily occurrence. During the six months from 24th June to 31st December, 1824, 250 men received *serious* hurts; and of these, during six weeks of that time, fifteen were seized with the disease under consideration, and twelve died. Such an occurrence had been unknown before. Of the cause it is impossible to speak with precision—whether a peculiar state of atmosphere; or whether contagion were imbibed at some common source, or whether it were carried, as is not improbable, by the medical attendants.

Referring to the section on *causes* for some further remarks on this head, let us come to the *symptoms* and local changes.

Diffused cellular inflammation may be set up at the seat of a local injury, and may spread continuously, involving the neighbouring parts. In this case, the chief symptoms are fever with great swelling and tension; most acute pain, without any, or with but little, of the surface redness of erysipelas.

In another set of cases, the diffused inflammation is set up at a distance from the part originally inflamed or injured, and without any direct continuity. This happens when, as we believe, the whole mass

of the blood is poisoned, as by a dissection wound, and the local disease is but a manifestation of pyæmia. After shivering, headache, and nausea, the patient is stricken with a most acute pain, generally in the axilla, or under the pectoral muscle, or above the clavicle. Slight puffiness follows, and great tenderness; some redness, perhaps, not of the deep erysipelatous hue, but of a pale peach blossom tint. The swelling becomes tense and shining; the pain agonising; the countenance haggard; the pulse very frequent and jerking; and there is usually intense restlessness and despondency, or delirium. Next, the swelling feels *boggy*; the skin vesicates, becomes mottled, and sloughs; and if cut through large quantities of seropurulent matter come out, with sodden flakes of areolar tissue. The disease may have several issues. It may prove mortal by the extent of the blood poisoning; or by the exhaustion consequent on gangrene, or may wear the patient out by slow suppuration, as is often the case after phlegmonous erysipelas.

This form of erysipelatous inflammation, not always having the outward redness to distinguish it, has been mistaken for acute rheumatism; from which it may be diagnosed by the depressed nature of the pulse and constitutional symptoms, and by the existence, which will usually be discovered in the traumatic cases, of a local injury.

One of the cases above recorded had its origin in a dissection wound. Other cases of the same kind will be related in the article WOUNDS.]

[*Prognosis.*—Erysipelas is a disease that can never be lightly regarded, and is often most dangerous. As in other diseases, the patient's chance of life will be in direct proportion to his strength, and inversely to the extent of mischief. The extremes of infancy and age, drunken and dissipated habits, and the existence of previous disease, especially of the kidneys or liver, tell very much against the patient. It will be bad for him, too, if erysipelas be epidemic and severe, and if he have contracted the disease by contagion or infection from some patient who has it severely. A very extensive attack, and large suppurations, are also dangerous, particularly about the head, or the throat, or scrotum, or anus, or lower extremities. But, after all, it is the pulse, the state of breathing, the state of the mind, and the power of taking nourishment and of procuring sleep, which will guide the surgeon's prognosis. There are three sources or periods of danger: First, from extensive febrile excitement, or constitutional irritation from poisoned blood in the early stage. Secondly, from the exhaustion of pain and confinement of matter. Thirdly, from general pyæmia and visceral inflammation, or from purulent absorption, diarrhœa, and hectic, or from the profuse discharge. If local swelling seem to subside, but the pulse continues quick, or quicker, and the tongue does not improve, it is ominous, for then a portion of areolar tissue may be sloughing, or some internal part may be attacked.

The remote consequences, even if life be preserved, are often very disastrous. A limb may be withered, shrunk, and useless; or there may be a general cachexia, and tendency to diarrhœa, dyspepsia, and phthisis, or what is very frequent after every form of erysipelas, the patient may be persecuted with a succession of boils or carbuncles, or with those rheumatic pains which are so common after scarlet fever.

Metastasis.—This word really means, that a

disease vanishes from one part and attacks another; but in its wider and more popular signification, it means that several parts are attacked successively. It is a common phenomenon in all blood disorders—nettle-rash, gout, and rheumatism, and in pyæmia, and the whole erysipelatous alliance. The tenth case of those which occurred in the Plymouth dockyard exhibited a metastasis of the former sort. Mr. Nunneley quotes the following, of which we give an abridged version.

A lady of 50, with erysipelas of the left foot: on the eighth day the foot became suddenly well, and within a few hours severe pain in the abdomen came on. Death in 24 hours. Intestines inflamed; sanious fluid in peritoneum.

A woman of 30, recovering from erysipelas of the throat, took laxative medicine, followed by pain in the abdomen, and death in 48 hours. Omentum inflamed; puriform fluid in peritoneum. *Quoted from Dr. Abercrombie.*

A young woman had erysipelas of breast; miscarried; was seized with symptoms of puerperal fever. Death. Bloody flabby liquid in peritoneum. *From Dr. Alison.*

A man æt. 27, had erysipelas, which supervened on syphilitic bubo. Tenderness of abdomen and vomiting of green bile were followed by death. *Post-mortem.* Lungs congested; turbid serum in pleura; abdominal viscera coated with lymph; serous effusion in peritoneum; petechiæ about kidneys; arachnoid opaque and serous effusion. (*Nunneley, op. cit. p. 89.*)

Mr. Bird gives two cases of translation—one from the leg to the face, another from the face to the thigh.

Morbid Appearances.—"After death," says Rokitsky, "the redness has generally disappeared, but the swelling is still perceptible; the epidermis is either easily separable, or actually separated, and the surface of the cutis is moist, and covered with a viscid and more or less puriform exudation. The redness is seen on a transverse section to be confined to the outermost thin layer of the cutis; the deeper layer is pale, and is somewhat infiltrated only when the inflammation is intense; the subcutaneous cellular tissue is then in like manner slightly infiltrated." (*Pathological Anatomy, vol. iii. Syd. Soc. Ed.*)

In the phlegmonous variety, and in the diffuse inflammation, the cuticle is wrinkled and vesicated, the skin gangrenous in patches; after death the areolar tissue will be found infiltrated with liquid, which, according to the severity and duration of the disease, will be pale or yellow serous, reddish and turbid, milky and semi-purulent, or a greenish pus; and the tissue itself reddish and vascular, or thickened and solidified by fibrinous effusion, or dead and rotten, like flakes of tow, or "wetted chamois leather," to which Mr. James compares it. The subjacent fascia may be destroyed, and intermuscular spaces infiltrated; or even portions of muscle may be invaded, and rendered pale, softened, or gangrenous; the veins and lymphatics, which pass by, reddened or suppurating. *Purulent depôts*, as they are called, may be found in the joints, or in the areolar tissue of various parts of the body, or in the viscera; in fact, the whole series of morbid appearances may be present which are common to the whole erysipelatous group of diseases, including puerperal fever, pyæmia, &c. &c. "In ten out of eleven cases of

dissection of the bodies of those who had died from erysipelas in the hospital of La Charité, in Paris, Dr. Corbin detected very decided lesions of the abdominal organs, principally of the mucous membranes of the stomach and intestines. Pus is not unfrequently disseminated through the viscera, principally in the substance of the liver. The frequency of these visceral affections in erysipelas has been particularly pointed out by Dupuytren, who says he has opened a heap of bodies (*foule de cadavres*) of those who have died in consequence of diffuse phlegmon, and that he has observed among those who perished, towards the end of the malady, the external inflammation itself was much less the cause of death, than an internal inflammation produced by some imprudence. Pleurisies, pneumonia, and abscesses of the liver, have been noticed, and these maladies have happened after the patient has exposed the face, neck, chest, or limbs to the cold." (*Nunneley, On Erysipelas*, p. 196.)

The *predisposing causes* of erysipelas are in general such as produce disorders of the digestive organs and impurity of the blood. Foremost amongst these stands intemperance, especially if combined with deficiency of solid food, loss of sleep, prolonged marching or other fatigue, exposure to the weather at unseasonable times, grief, and those other influences which under any circumstances produce a low and irritable state of system. But it is probable that many of these conditions rather give rise to low or atonic inflammation, than to genuine erysipelas.

Some persons there are who are constitutionally predisposed to it. Thus, one attack, so far from conferring any exemption, only seems to render the patient liable to repeated attacks. Women are said to be more subject to it than men; although probably it is rather to slight erythema, caused by cold, or delay of the catamenia, than to real erysipelas.

Every sort of injury or abrasion may invite an attack of erysipelas, more especially those which are irritated, or in which the exudations are disturbed, and, speaking generally, those which have most tendency to inflammation. It is of no avail to give a list, because the simplest prick or cut will give occasion for erysipelas, if the wound be infected, or the blood.

In some cases of traumatic erysipelas the local symptoms precede the constitutional. The same may be the case in all inoculated diseases.

But no injury can produce erysipelas without the presence of a peculiar poison in the blood; of which we may assume, that

I. The erysipelatos condition in some cases arises spontaneously, or idiopathically, or primarily; possibly from changes of temperature acting upon a system predisposed.

II. It may, without doubt, be generated by putrid miasma, under certain conditions.

III. The putrid miasm which generates erysipelas is capable of generating also each of the other forms of disease which we have enumerated as belonging to the erysipelatos alliance, and which are all included in the general term pyæmia, viz., purulent depôts, puerperal fever, deaths by shock or adynamia after operations, phlebitis, and inflammation of the lymphatics, some forms of sore throat, and of diarrhœa and dysentery.

IV. Each variety of erysipelatos disease may

generate every other, by contagion and infection, using those words in the fullest sense they admit of: contagion being the application of liquid or solid poison, by the touch or by inoculation; and infection being the effect produced by inhalation of gaseous poison into the lungs, or the contact of vitiated air with a wound or ulcer.

Respecting the first proposition, it must be remarked that there are some individuals so predisposed, that errors in diet, trifling injuries, and exposure, readily produce slight attacks of erysipelas, which seem to bear the same relation to the graver forms of the disease that febricula does to typhoid fever; of which it cannot be proved that they arise from outward miasm, and which, under favourable circumstances of cleanliness and ventilation, soon subside, and do not propagate themselves.

The proofs of the second and third propositions have been accumulating during the last century and a half at the least, and are now so numerous that the task of selecting instances is difficult; and so overwhelmingly convincing that it is a point little creditable to the physicians and surgeons and managers of public institutions, that the disease is still permitted to continue its ravages, even in a mitigated form.

Whilst writing, the reviser of this article receives a report from Dr. Dundas Thomson, medical officer of health for Marylebone, dated August, 1859, stating that three virulent cases of erysipelas occurred in succession on the first floor of the west wing of the Middlesex Hospital. One of the sisters complained of an offensive smell in the ward. This aroused the suspicions of Dr. Corfe, who found that the post-mortem room was immediately below, so that effluvia could enter, and still more, that the waste-pipe of the room was untrapped, and that it communicated with a cesspool and choked drain. The cesspool was filled up, the drain cleansed and trapped, and for the 12 months since not a single case of erysipelas has occurred in the ward.

All experience tends to show that the most frequent source of erysipelas is that kind of poisoned atmosphere engendered by the exhalations of the sick and wounded. Dr. George Gregory read a paper on the subject before the Med. Chir. Soc. (reported in *Lancet*, 1848, vol. ii.), in which he called the general condition of disease produced under such circumstances *ochlesis* (from ὄχλος, a crowd), and described erysipelas of the face, and every other variety of creeping, low, diffused inflammation, as the normal results.

In a conspicuous metropolitan hospital, the reviser of this article once witnessed an operation for aneurism. The patient died of low inflammation in a week. One of the hospital functionaries remarked afterwards, "I knew the patient would die, and I implored the operator to put him into a different bed, but he would not; he does not believe in sanitary measures. Every patient in that bed dies; it receives all the fumes of the water-closets."

"Of the connection between erysipelas and puerperal fever," says Dr. Ferguson, "I may say that those two maladies are generally co-existent in our hospital, and that when the mothers die of puerperal fever, their infants perish of erysipelas." (*On Puerperal Fever*, Lond. 1839, p. 29.) The mortality from puerperal fever in lying-in hospitals

is too wide a subject for us to venture on, but whatever is true of these hospitals as causes of fever, is true in its degree likewise as regards erysipelas.

Mr. Coulson quotes from Malouin, to the effect that "out of twenty females who were confined in February, 1746, in the lying-in ward of the Hôtel Dieu, scarcely one escaped being attacked with puerperal fever, and that erysipelatous affections were equally common." In the spring of 1750, puerperal fever was again epidemic, when its connection with erysipelas was noticed by Pouteau in his "*Mélanges de Chirurgie*." This disease again prevailed as an epidemic in 1770, and is mentioned by Dr. Leake. Three years after, we find it devastating the lying-in ward of the Edinburgh Infirmary, and Dr. Young, then professor of midwifery, accounts for it by the contemporaneous existence of erysipelas, which not only attacked the parturient, but the wounds of those who had undergone any operation.

After alluding to the testimony of Dr. John Clarke in 1787 and 1788, and of Dr. Gordon of Aberdeen, and of Hey of Leeds in 1811 and 1812, to the effect that puerperal fever and erysipelas prevail together, Mr. Coulson gives it as his opinion "that epidemic puerperal fever is at times of an infectious erysipelatous character." (*Coulson, On the Hip Joint*, &c. 2nd ed. Lond. 1841.)

The late Mr. Storrs, of Doncaster, (in the *Provincial Med. Journal*, 2nd Dec. 1843,) published an appalling series of cases in which erysipelas had given rise to puerperal fever, and the converse. For instance, Mr. Reedal, of Sheffield, was attending a case of sloughing bubo with erysipelas, in a young man. The patient's sister, who waited on him, was seized with erysipelas of the head, and died. Five parturient women, whom Mr. Reedal went to from the house of the patient, died of puerperal fever; one other was attacked with inflammation of the mucous membrane of the bowels. Two fatal cases are recorded of puerperal fever caused by infection from erysipelas in the practice of Mr. Sleight, of Hull. Mr. Hardy, of Hull, attended twenty women between March 21st and April 20th, 1838, of whom seven died of puerperal fever. He was at the same time attending a case of large sloughing ulcer of the groin, and one of erysipelatous abscess of the breast. At the same time, to show the atmospheric condition, large numbers of pigs, sheep, and cattle died in parturition. Three surgeons in the same town performed a post-mortem examination in a case of gangrenous hernia: each had cases of puerperal fever. A physician of Boston made the autopsy of a man on March 19th, who died after forty-eight hours' illness, of œdema of the thigh and gangrene. He wounded his hand, and was laid up from the 20th March to the 3rd April. But on 20th he attended a woman, and she died; as did five others out of seven whom he attended in the following winter. The nurse who laid out the third parturient woman died of erysipelas; and the nurse who laid out the fourth died after twenty-four hours' illness. In August, 1836, a practitioner had three fatal cases of puerperal fever; his assistant took fever and foul ulceration of the throat. Mrs. Pearson laid out the body of a child who had died of gangrene of the navel; was confined a few days afterwards, and died. Her child died of erysipelas. The sister of one puerperal patient of Mr. Storrs had herpes, typhoid erysipelas, and a huge

abscess in the mamma. It is far more easy to go on with such evidence than to stop. Mr. Elkington, of Birmingham, (*Prov. Med. Journ.*, 13th Jan. 1844) in 1833, after visiting a bad case of erysipelas, attended five women, four of whom died. Mr. Nason, of Nuneaton, after seeing one of Mr. Elkington's patients, attended a woman, who died, whose husband had sore throat, and whose friend had a severe feverish attack. Two of the female attendants on the other patients had erysipelas. Mr. Perry, a patient of Mr. Elkington, had severe erysipelas in 1835, which was the means of conveying contagion to one woman, who died. In Perry's house, which had not been purified, Mrs. S. was attacked by puerperal fever in 1839, her husband had sore throat, and her infant erysipelas.

That erysipelas is capable of spreading by infection, and *à fortiori* by contagion; and that it can be generated by putrescent matter in certain states; and that the same cause may produce a *very low state, in which patients sink after operation with little or no post-mortem change*, is proved by the following cases. Mr. Erichsen (*Science and Art of Surg.* Lond. 1853, p. 348) says that his wards at University College Hospital had been free from erysipelas for some time, when on 15th Jan. 1851, at noon, a man with gangrenous erysipelas of the legs was placed in Burdett's ward. Two hours afterwards, Mr. E. ordered the man to be removed, and the chlorides to be used. Notwithstanding this precaution, the patient in the next bed, with necrosis of the ilium, was seized with erysipelas in two days, and died of it. The disease then spread to almost every patient in the ward, and proved fatal to several. But in several instances patients were affected with the constitutional symptoms, the fever and gastro-intestinal disturbance, *without any manifestation of local symptoms whatever*.

The relation of the *diffused*, or *erysipelatous* inflammation of the areolar tissue to cutaneous erysipelas is very evident from the case of Mr. Newby (quoted in *Travers, On Constitutional Irritation*, and in *Nunneley, On Erysipelas, from Dr. Nelson*), a surgeon, who, on June 1st, pricked his thumb in examining the body of a child which had died of enteritis and erysipelas of the abdomen. On the following three days he complained of depression; on the fourth, of headache and fever, with a small pustule on the thumb, and slight pain in the axilla; on the seventh, deep-seated pain in the left breast, which assumed a pink tinge; axilla and arm more uneasy; on the eighth, increased inflammation of the breast, and great feebleness; death on the twelfth day. During Mr. Newby's illness, his assistant had inflammation of the fauces of erysipelatous appearance, and suppuration of the tonsil. His pupil had low fever; the housemaid cynanche tonsillaris; the nurse an attack of pyrexia, followed by phlegmonous erysipelas, of which she died. A woman who assisted in the room after Mr. Newby's death had phlegmonous erysipelas, but recovered.

Here is another case, showing, as Mr. Nunneley observes, that diffuse inflammation and erysipelas are one and the same disease. James Craig, whose master had just died of some febrile disease, was brought to his father's house with erysipelas of his face. The disease was severe, spread to chest and abdomen, and led to extensive suppuration. Vent was given to the matter, and he recovered. His father was attacked in both hands and arms; the disease spread to his face, and after

his death, extensive suppurations were discovered along the back and loins, from the neck to the sacrum. (Quoted from *Gibson, Edinburgh Med. Chir. Trans.* vol. iii. p. 96.)

That erysipelatous inflammation of the throat and fauces has a common origin with the other members of the alliance, may be seen from incidental notices of sore throat in the preceding cases. It is proved more fully by the reports of several epidemics, collected by Mr. Nunneley, in which the association of livid, or dusky, or sloughing, or croupy sore throats with erysipelas, and their ultimate origin from the same causes, is plainly set forth. (Op. cit. p. 107, &c.) See also case of erysipelas of the mucous membrane of the throat, fatal from submucous serous infiltration, with false membrane, and evidently epidemic, if not contagious, (in *Travers, Further Enquiry*, Lond. 1835, p. 160.) See also the case of a young man, nursing his mother ill of erysipelatous sore throat, when he was smitten with an offensive fume, and was seized with diffuse cellular inflammation of the trunk, of which he died. (*Graves's Clinical Medicine*.) In fact, there is no lesion common to the *pyæmia* group which may not be met with in erysipelas.

Mr. P. H. Bird (*On the Nature, Statistics, &c. &c. of Erysipelas*, Lond. 1858) met with sore throat in 60 per cent. of the cases of idiopathic erysipelas of which he has notes.

Dr. Gross (*System of Surgery*, Philadelphia, 1859) says that in 1844, '45, and '46, the disease was so common in the Louisville Hospital, and also throughout the city of Louisville, that no operations were performed save of necessity. Whole families were sometimes cut down by it. Every case of disease admitted into the Louisville Hospital received its peculiar impression, and "wore its livery." When the affection was at its height, many patients convalescing from other diseases were suddenly seized with diarrhœa, pneumonia, and bronchitis, over which the usual remedies exercised no control.

Dr. Gross also describes a peculiar and most fatal epidemic of erysipelas which prevailed from 1842 to 1847 in various parts of the United States, particularly the south-western, and in Canada. It was known by the names, "black tongue," "swelled head," and "erysipelatous fever." It began in the throat, with a deep red glossy swelling, which extended to tongue, uvula, tonsils, and face, which was most hideously swollen and distorted. Delirium and prostration accompanied it from the first. Some died early; others from local sloughing; others from *pyæmia* and abscesses in the lungs and other parts; if lying-in women were attacked, they usually exhibited high evidence of metritis, peritonitis, and phlebitis. In one instance, the immediate cause of death was a large abscess in the left lung, erysipelas being seated in the corresponding leg.

The following example of the connection of *pyæmia* and phlebitis with diffuse inflammation and phlegmasia dolens is most instructive. It is taken from *Travers, Constitutional Irritation*, Lond. 1826, p. 374. Mrs. C., æt. 40, mother of a family, and suckling, complained on 12th October, 1825, of redness and pain of the knuckle of her middle finger, and slight fever. A slight recent wound on the metacarpus. On the 14th, pain and heat all up the arm and neck. Slight fulness and tenderness above clavicle. That night delirium. 16th.

Violent delirium; fulness and tension over flexor tendon of middle finger; which was laid open and yielded a teaspoonful of healthy pus. "There was no absorbent nor glandular inflammation, nor any cutaneous blush, but a little more fulness from the elbow upwards, and about the subclavian region, than on the opposite side." Bleeding to 20 oz.: ten gr. of calomel, epsom salts, and jalap. The blood was slightly buffed and cupped. At night antimony and laudanum. 19th. No rest; delirium unabated. Two or three faint lines of inflamed absorbents on forearm, which was puffy, and tender when grasped. Pulse very rapid. Bleeding to 12 oz., "which occasioned a sensible depression;" more calomel and salts; opium at night. 20th. More tranquil; pulse as rapid, but softer; leeches and anodynes. 21st. Hysterical and feeble, but tranquil and rational. 22nd. A quiet but sleepless night; profuse sweating; bark and acid. Up to 25th seemed improving, though the pulse remained at 130 and upwards; great nervous debility; bark and opium, and a moderate quantity of wine, which was "withdrawn because it seemed to overstimulate." 28th. A violent rigor, followed by profuse colliquative sweating. 29th. Another rigor. 31st. Death. The wound in the finger continued to discharge freely, and the hand was free from pain. On post-mortem examination, a small quantity of pus found in the tendinous sheath of the forearm; a straw-coloured serum exuded into the upper arm; the humeral and axillary vein plugged with coagulum. The viscera not examined.

The maid servant who fomented Mrs. C.'s hand suffered from abscesses in the hand and forearm, and above the inner condyle of the humerus: restlessness, delirium, and phlegmasia dolens of both legs.

The laundress who washed Mrs. C.'s sheets, in opening them, turned pale as death and complained instantly of pain in the axilla. Nausea; faintness, rigors and delirium followed; and a deep and extensive abscess above the left breast.

If we recur to that remarkable series of cases which occurred in the Plymouth dockyard, we shall see that out of the fifteen patients, each of them suffered evidently from the same cause; two died from intense fever, without adequate local change to cause death; ten had symptoms of phlegmonous erysipelas, or of the diffused inflammation locally; and three died of visceral or distant disease, without local symptoms at the spot by which the poison entered the veins. From one and the same poisonous source, whatever that was, every variety of erysipelatous disease proceeded. Every feature of *pyæmia* and puerperal fever was produced.

We have thus laboured to show, that the "*irritation*" of Hunter and Travers, and the "*constitutional susceptibility*" and "disorder of the chylopoietic viscera" of Abernethy, are figures of speech, which, in modern language, are rendered by the term impurity of the blood. And in the mass of evidence we have presented of the origin and alliances of erysipelas, we have shown how the simpler cases arise from the common causes of illness, especially if aided by cold, or blight, as it was called in Sydenham's time, and that the deviation from the sthenic, or healthy adhesive inflammation may be slight; whilst the graver cases arise from the workings of a putrid poison. Here the question arises, will *any* putrescent matter suffice? or is there anything *specific* in the cause of

erysipelas, as there is, for example, in the cause of syphilis?

In answer to the former question it must be said, that putrescent matter evidently requires some atmospheric conditions to be superadded, of which we know nothing, in order to create the erysipelatous poison; and to the second, that there seems every reason to believe that once having arisen by any means, it possesses the power of propagation just like the diseases called specific.]

[*Treatment.*—In treating this branch of the subject, we will first give a short *catena* of the opinions of eminent men at various epochs; and then sum up the measures expedient in each variety of erysipelas.

Hippocrates says that cold water is of use in erysipelas, but not if ulcerated; Celsus prescribed blood-letting, if the strength permits; then refrigerants and astringents, such as Cimolian chalk and water, covered with a leaf of beet, (a remedy which the vulgar use to this day, in the form of fullers' earth and water). Galen and his followers adopted maxims of the soundest. Since, says he, refrigeration is dangerous in common inflammation without evacuation, much more is it so in erysipelas, in which there is danger lest the bile be diverted to some nobler part; so instead of venesection, we use cholagogue medicines; then cooling applications; and if the colour becomes livid, warm poultices, or fomentations of salt water. (*Galen, Meth. Medend., Op. Om. Kühn, vol. x.*) Serjeant Wiseman says, that if it fall upon the head or throat, phlebotomy is permissible, to avoid phrenitis or squinancy; but if it be simple, and only in the skin, we ought only to evacuate the redundancy of humours, and prevent the ebullition of choler. If it arise from a wound, cooling and lenient applications are permissible, if preceded by purgatives; but in erysipelas of the head and face, the greatest caution is necessary in the use of repellants. Sydenham considers that in this disease peccant matter is mixed with the blood, and must be evacuated; also, that the ebullition of the blood must be regulated by cooling remedies; also, that matter which has become impacted in the parts must be discharged and eliminated. To do this, he bleeds freely, and finds the blood like that of pleurisy the next day, then gives a mild cathartic, and a paregoric draught of syrup of poppies at night. The purging being over, an emollient fomentation was used warm twice a day; and after the fomentation, an application of a stimulating tincture of Venice treacle, that is, pepper and cloves with spirits of wine. The patient lives on barley water, gruel, and toasted apples, with a little of the smallest beer. Usually, says Sydenham, the purging and bleeding suffice. This treatment evidently applies only to mild idiopathic cases of a sthenic sort.

Cullen, whose experience, like Sydenham's, was medical and not surgical, treated erysipelas of the face by bleeding and antiphlogistics; but confessed that the disease might be attended with putrid symptoms, and require bark, though he had never seen such cases. John Hunter, in cases of diffused inflammation in irritable habits, was averse to much bleeding, and recommended bark. Abernethy believed the erysipelatous group to be produced rather by something wrong in the constitution of the patient, which predisposed, and particularly disorder of the digestive organs, than by inoculation of poison. He gave alteratives, and was averse

to bleeding.] The most modern advocate of bleeding is, or was, Mr. Lawrence, whose opinions at the date 1828 were that as erysipelas resembles other inflammations in its causes, symptoms, and effects, it should be treated on the same principles; that is, on the antiphlogistic plan. Venesection, local bleeding, purging, and low diet are the first measures, to which saline and diaphoretic medicines may be afterwards added. He says, the earlier these means are employed the better: vigorous treatment in the beginning seems to him most calculated to shorten the attack, and prevent the disease from spreading beyond its original seat. At the same time, he admits, that as the skin and cellular texture are of secondary importance, it is not so urgently necessary to arrest inflammation in them, as in the vital organs; neither does the same reason for very active treatment exist as in affections of the eye, where a slight change of structure may seriously impair the utility of the organ essential to our comfort and pleasure; but the extensive suppuration and mortification, which erysipelas sometimes produces, may render a limb, in a great measure, totally useless, or may even destroy life. "The disposition of erysipelas to terminate by resolution, is another reason against resorting indiscriminately to active depletion. In many cases, the disease passes through a certain course, and ends spontaneously: it is sufficient to put the patient on low diet, to clear the alimentary canal, and then to use mild aperients and diaphoretics. When it proceeds, as it often does, from an unhealthy condition of the alimentary canal, the removal of the internal disorder leads to the cessation of the local complaint. It must, however, be observed, that venesection is sometimes useful both in curing the internal cause and in promoting the termination by resolution." Mr. Lawrence afterwards observes, that he does not mean to recommend that measures equally active, and, in particular, that bleeding, whether general or local, are to be employed in all cases. In young persons, in the robust, and those of full habit; in instances where the pulse is full and strong, or where there is headache and white tongue; in erysipelas of the head, attended with symptoms denoting affection of the sensorium, and more especially in the very beginning of the affection, venesection will be proper; and it may be necessary to bleed largely, to repeat the evacuation, or to follow venesection by local abstraction of blood. Under such circumstances, the other parts of the antiphlogistic plan must also be employed, that is, the alimentary canal should be cleared by an active purgative, which may be followed by salines and antimonials, with the occasional use of milder aperients; and low diet should be enjoined. As Mr. Lawrence adds, nothing can be more different from such a case, than that of an elderly person, with a small and feeble pulse, in the advanced stage of the disease. The interval between these extremes is filled by numerous gradations, requiring corresponding modifications of treatment. The antiphlogistic plan itself embraces a wide range in point of degree; from blood-letting local and general, with purging, vomiting, the free use of mercury and antimony, and low diet, to the exhibition of a mild aperient, with some saline medicine. Mr. Lawrence believes, that the treatment of erysipelas, like that of any other inflammation, should be modified according to the age, constitution, previous health, and habits of the

patient, and the period of the complaint. "When the affection occurs in old and debilitated subjects, the powers of life are soon seriously impaired, and our efforts must be directed rather towards supporting them, than combating the local affection. I have often seen such subjects, labouring under erysipelas of the face in its advanced stage, with rapid and feeble pulse, dry and brown tongue, recovered, under circumstances apparently desperate, by the free use of bark and wine." The same writer deems local bleeding sufficient in the milder cases of erysipelas, and often necessary in the more severe ones, as an auxiliary measure. Cupping, when practicable, he sets down as more efficacious than leeches, though objectionable on account of the painful state of the skin. Leeches, he remarks, when applied to the sound skin of some individuals, produce an effect analogous to erysipelas, but they exert no such influence over the inflamed skin, to which they may be applied freely and safely. In order to produce any decided benefit, he thinks they should be applied in large numbers.

Mr. Lawrence adds, that after the inflammation has been checked, the surgeon should not be in too great a hurry to prescribe tonics, stimulants, and a full diet. "Medical practitioners in general (says Mr. Lawrence) are anxious to begin the strengthening plan; they seem to have the fear of debility constantly before their eyes, and lose no time in directing the employment of bark, and recommending animal food, with beer or wine. In this way relapses are frequently produced; the inflammation and fever are renewed; further local mischief is caused, and recovery is retarded." When it is doubtful whether stimuli should be employed or not, he deems subcarbonate of ammonia the best medicine. Bark comes next in order to it, and the sulphate of quinine is the most eligible preparation. Wine is sometimes necessary; but Mr. Lawrence thinks it should be given sparingly. (See *Med. Chir. Trans.* vol. xiv.)

[The reviser of this article thinks it right to repeat these portions of the former edition, inasmuch as they contain the materials for a history of opinion and practice in medicine. But it is necessary to add, that the illustrious surgeon referred to does not now hold the antiphlogistic doctrine here described. Not indeed that he is likely ever to have bled, where bark and wine ought to have been given; but in an interview with which he favoured the reviser, he stated as his present opinion that treatment should, as a general rule, be decidedly tonic and supporting.

The full force of the antiphlogistic treatment, employed, as it was at a time when all humoral pathology was in abeyance, and inflammation and increased action were the popular bugbears, is exhibited in the series of cases which we have abridged from Dr. Butter. How remarkable it seems that patient after patient should have been submitted to exactly the same treatment: bleeding as long as blood would flow; purgation till blood passed from the irritated bowels; and wine only when subsultus tendinum announced the near approach of death. For example, in *Case 5*, after leeches, cathartics, tartar emetic, and bleeding; here is an extract.

"Eight o'clock, P.M. Fever again increasing; erysipelas extended even to the knee; the integuments over the tibia looked mottled or variegated, like the colours of a rainbow; red lines and patches were also seen to run up the limb to the groin.

Tension very great. Delirium. Venæsectio ad $\frac{3}{4}$ xvi. Ten o'clock, P.M. Not relieved; headache most severe. Rep. V. S. ad $\frac{3}{4}$ xxiv." It must be remarked, that Dr. Butter, throughout his work, shows the most advanced and sound views, and repudiates all this cruel practice, of which he shows the bad results.]

In *bilious* erysipelas, or that originating with strongly marked gastric disorder, Desault gave, in the first instance, a grain of tartarised antimony dissolved in a considerable quantity of fluid. He had seen the symptoms entirely subside, although the medicine produced no other sensible alteration in the animal economy than an increase of the insensible perspiration and urine. When the symptoms resisted these evacuations, he was obliged to have recourse once or twice, or even more frequently, to the emetic mixture. When the erysipelas was cured, and the bitterness in the mouth and fever had subsided, two or three purges of cassia and manna, with a grain of emetic tartar, were exhibited. As soon as the symptoms were mitigated, the diet of the patient was allowed to be more generous. In *bilious* erysipelas, Desault observed, that the cases of the patients who had been bled previously to their admission into the hospital, were invariably the most obstinate.

When the tongue, without being red at its point and margins, was furred, and marks of gastric disorder prevailed, unattended with tenderness of the epigastrium, Dupuytren found emetics useful. (*Clin. Chir.* t. ii. p. 320.)

In cases of *bilious* erysipelas, many modern practitioners, says Mr. S. Cooper, would be bolder with antimonials than Desault, first, by imitating Richter, and giving an emetic at the commencement of the attack, and then by exhibiting more freely either antimonial powder, or tartarised antimony, with a dose or two of calomel.

In *phlegmonous* erysipelas, Desault was an advocate for bleeding in the beginning of the disorder, and this practice he followed up by the administration of tartarised antimony and evacuants.

In the beginning of *phlegmonous* erysipelas, Dupuytren likewise had recourse to general and local bleeding, emollient applications, or, what he considered still more efficacious, cold sedative lotions. If inflammation of the cellular texture had begun, he not only practised these antiphlogistic measures, but repeated them. But if there was a narrow wound, seemingly attended with strangulation of the parts, he made a simple or crucial incision without delay. (See *Clin. Chir.* t. ii. p. 320.)

[But side by side with the extreme antiphlogistic school of the last century there was one which saw in erysipelas and its allies the characters of putridity or malignity only, and which repudiated evacuants, and employed tonics and antiseptics.] Dr. George Fordyce declared that he always found bleeding and evacuations hurtful, and Peruvian bark the best remedy. "It should be exhibited (he says) in substance, if the patient's stomach will bear it, and in this disease it will almost always bear it, and in as great a quantity as the patient's stomach will bear, which is commonly to the quantity of a drachm every hour!" (*Trans. of a Society for the Improvement of Chir. Knowledge*, vol. i. p. 293.)

Dr. Wells was also an advocate for the treatment recommended by Fordyce.

[The tincture of sesquichloride of iron has been recommended of late years by Dr. Ranking and others. The reviser has seen it of eminent service in an apparently hopeless case of puerperal fever with diphtheritis, which he attended in consultation with Dr. Frere, and in which, when the patient seemed evidently dying, she recovered under the use of this tincture in immense doses—one or two teaspoonfuls every two hours.

Of local measures the most important in the phlegmonous and diffuse erysipelas are *incisions*, which, relieve the tension, give vent to exudations and to blood, and hinder the exudations, which, as James says, are neither walled in by adhesions, nor discharged by pointing, from spreading and contaminating sound parts. The older surgeons, if men of genius, always used them, more or less. Le Dran is very explicit: "*Of a gangrene proceeding from an erysipelas*," he says, "the fluids fermenting require a larger space to act in, and the skin being of too close a texture to yield immediately to this increased bulk, will compress the parts which it contains, hence the adipous parts mortify, and a putrid serum diffuses itself over the limb." In this case, he continues, we must discharge the putrid serum by incisions. These, he says, should be made right through the diseased parts to the quick; and they should be carried lengthwise into the inflamed part surrounding the gangrene. They should be about two inches long, and an inch distant. If necessary, others may be made below, but rising partially into the intervals. (*Le Dran, translated by Gattaker. Lond. 1752.*) Baron Boyer gave the same advice. (*Traité des Mal. Chir. t. ii. p. 22.*)

It is, however, one thing to propose a remedy; quite a different, but equal credit belongs to him, who without being the first discernor, yet is the first to obtain universal sanction and the stamp of authority for it. This credit belongs to Mr. Copland Hutchinson, formerly surgeon to the Naval Hospital at Deal, where seafaring men are very liable to phlegmonous erysipelas of the legs, ascribed to the irritation of the salt water, and the friction of their loose coarse trousers. In this description of patients, the disease frequently proceeds rapidly to the gangrenous state, and the consequence is the loss of many lives and limbs. Even when the danger of mortification is avoided, abscesses often occur, which spread between the muscles and under the integuments to a surprising extent: "from the ankle to the trochanter, and over the glutæi muscles." In the first few cases which came under the care of Mr. Hutchinson, this gentleman's plan of treatment, in addition to the usual medical means, consisted of local bleeding by means of cupping glasses, followed by fomentations. Subsequently, however, he adopted the method of making several free incisions with a scalpel on the inflamed surface, in a longitudinal direction, through the integuments, and down to the muscles, as early in the disease as possible, and before any secretions had taken place. These incisions were about an inch and a half in length, two or three inches apart, and varied in number from six to eighteen, according to the extent of surface which the disease is found to occupy. Mr. Hutchinson states, that these incisions will yield between fifteen and twenty ounces of blood, and

give relief to the tense skin, at the same time that they form channels for the escape of fluid, and the prevention of bags of matter. After the operation, fomentations, or saturnine lotions, were employed.

By the preceding kind of treatment, Mr. Hutchinson found the fatal termination of the disease rendered less frequent, and gangrenous mischief wholly prevented. He adds that he never lost a case in the Deal Hospital for the last five years, during which the practice was followed. (*See Med. Chir. Trans., 1814, vol. v. p. 278, &c.*)

Instead of several moderate cuts, Mr. Lawrence thought the most powerful means of arresting the complaint was making one or more long incisions through the inflamed skin and the subjacent adipous and cellular textures. These incisions, he asserts, are followed very quickly by relief of the pain and tension; and this alleviation of suffering, he assures us, is accompanied by a corresponding interruption of the inflammation, whether it be in the stage of effusion, or in the more advanced period of suppuration and sloughing. Mr. Lawrence further maintains, that this treatment is employed to the greatest advantage at the beginning, since it prevents the further extension of inflammation, and the occurrence of suppuration and sloughing. At a more advanced stage the incisions limit the extent of suppuration and gangrene; and, at a still later time, they afford the readiest outlet for matter and sloughs, and facilitate the commencement and progress of granulation and cicatrization. (*Med. Chir. Trans. vol. xiv. p. 67, &c.*)

Respecting the treatment by incisions, Mr. Samuel Cooper thus delivered his judgment in the earlier editions of this Dictionary. That the practice of incisions with moderation and judgment has been the means of saving many limbs and lives, I consider as fully established as the opposite fact, that immoderate incisions have occasionally accelerated the patient's death. I have heard of instances in which a cut was made from the shoulder down to the hand, or from the trochanter major to the foot. Whoever looks over the reports of the consequences of incisions of immoderate length, as detailed in the *Lancet* and other works, cannot fail to be struck with the following facts:—Several patients, treated in this way, instead of being saved, went out of the world in a very sudden manner, sometimes from the shock of an enormous wound on the constitution in its disturbed state; sometimes from profuse hæmorrhage. In one or two instances, the cutaneous nerves, as well as large veins and arteries, were not spared, and a partial paralysis ensued.

I know of more than one case in which the patient died of hæmorrhage in a few minutes after an immoderate incision had been made. Dr. M'Dowel, a decided advocate of free incisions, candidly relates the following fact:—"The following case (says he) I witnessed ten years since; and at a more remote period than this, incisions in phlegmonoid erysipelas were constantly practised. A strong and healthy young man had severe phlegmonoid erysipelas of the leg, after an injury of the patellar bursa. The limb, from the foot to half way up the thigh, was enormously swollen, extremely tense and painful. There was high inflammatory fever. A free incision was made in

the leg through the fascia, which retracted widely after its division; the parts were much gorged with blood, and disorganisation of the cellular membrane and aponeurosis had commenced at one part. There was profuse bleeding from the entire almost of the cut surface. The extent of bleeding was not attended to by the person in charge of the case, and in twenty minutes life was nearly extinct. Every plan of stimulation and support was adopted, except transfusion; but death occurred in an hour and a half after the operation." (*M'Dowel, in Dubl. Journ. of Med. Science*, vol. vi. p. 179.) This case teaches us, at all events, that the bleeding must not be neglected. I am of opinion, therefore, says Mr. Cooper, that incisions of preposterous length are not the most prudent practice; by preposterous, I mean such as require a foot ruler or a yard for their measurement; for nobody is more convinced than I am that free incisions of less extent are often of the highest service.

[The controversy is forgotten now; yet, thirty years ago, Mr. Lawrence and the author of this dictionary were engaged in a severe pen and ink battle as to the length of incision.]

As a substitute for incisions, Sir W. Dobson proposed many small punctures, which he repeats twice a day to the number and extent required; and often, in bad cases, three or four times in the twenty-four hours. The quantity of blood and serous fluid discharged from these punctures, although sometimes considerable, he says, need never create any alarm. (See *Med. Chir. Trans.* vol. xiv. p. 206.)

There is no doubt that such punctures, whether merely deep enough to draw blood from the skin, or to let out some serosity from the subcutaneous tissue, give great relief when the skin is very tense. [In some cases they are very painful, and, in fact, more painful and less effectual than incisions.]

Mr. Lawrence now advocates one free and early incision; not many; not yet of extravagant length. The patient must always be watched, to take measures against excessive loss of blood.]

Leeches, and even cupping, have been at times employed to draw blood from the inflamed part—sometimes with relief in sthenic cases, but they are almost, if not quite, disused at present.

[Cold applications are decidedly to be condemned when they cause any feeling of shivering or discomfort; and in cases of idiopathic erysipelas they are objectionable on *à priori* grounds. The cases in which they are applicable seem to be those of slight erysipelas or erythema, threatening an inflamed wound, when the patient likes them; but in all cases tepid or warm are safer.]

Blisters, inapplicable as they seem, have been largely used, particularly by the English of 150, and the French of 50 years back. There seems no reason to doubt that they occasionally cut short a wandering and declining erysipelas, and at least they imitate the vesications of the disease. But the reviser would be very unwilling to sanction so barbarous a remedy. (See *Roche and Sanson, Nouveaux Elém. de Pathol. Méd. Chir.* t. i. p. 352.)]

A large blister was sometimes applied by Dupuytren over a wound, and to the surrounding skin; and he found that the irritation and suppuration

which were thus excited, occasionally succeeded in preventing phlegmonous erysipelas. (See *Clin. Chir.* t. ii. p. 320.)

Indeed, it was only for the prevention of the disorder that Dupuytren sanctioned this practice, which, as he particularly explains, he was afraid of resorting to, after the disease had resisted bleeding and cold sedative lotions, because he had sometimes, though not often, seen sloughing produced by it. (*Ib.* p. 322.)

The application of the nitrate of silver in substance, or in the form of a lotion, so as to blacken the part, was proposed some years since by Mr. Higginbottom, as a means of checking the peculiar action of the vessels, on which erysipelatous inflammation was believed at that day to depend. It was said to repress the effusion of serosity in the cellular tissue; and, if applied beyond the erysipelas, to form an obstacle to its spreading in any particular direction. By forming a black line with it, the inflammation may thus be kept from running up the neck to the face and head. (*On the Use of Nitrate of Silver.*) In the early stages of erysipelas, Mr. S. Cooper often employed it with advantage in the North London Hospital. Experience has since shown, that although the application will sometimes give the *coup de grâce* to a languid eruption, yet that it has no certain power of preventing erysipelas from spreading. Mr. Higginbottom directs the part to be first washed with soap and water, and then dried. The inflamed and surrounding skin is then to be moistened, and the nitrate of silver passed over it once, twice, or thrice, or more frequently, if rapid vesication be required. The part is then to be exposed to the air and kept cool.

[Mr. Lawrence uses a solution of 30 grains to a *drachm*; for the purpose of checking exudation into the tissue of the eyelids; and of drawing a line of demarcation round the inflamed part: and has great faith in its efficacy.]

Stimulating applications, such as the pepper and spirit lotion of Sydenham, soap liniment, solution of carbonate of ammonia, and the like were used, even up to a late date, and perhaps are now, to get rid of the last stage of simple erysipelas of the head. The tincture of iodine has been used largely by Mr. Norris. (*Med. Times*, Dec. 10, 1852.)

The *sulphate of iron* in solution (3iv. to a pint), was employed by M. Velpeau as a lotion, in order to act on the blood in the inflamed tissues. In the course of some clinical observations (*Med. Times and Gaz.* March 10, 1855) that the efficient cause of erysipelas is decomposition of the fluids at the injured part, whether primary, or caused by infection. These altered fluids spread by imbibition into the adjoining tissues. To attack them is therefore to extinguish the disease in its focus; that is in cases of local infection. M. Velpeau believes that the iron lotion thus cuts short the erysipelas. At least it iron-moulds the linen.

Of other remedies on our list, M. Velpeau gives an opinion in which we fully concur. In twenty-five cases he had employed compression by bandages with no good result. In thirty-three flying blisters were applied with equal want of benefit. The same with the nitrate of silver in thirty cases. In 200 cases mercurial ointment was resorted to, and sometimes seemed to diminish the duration of the disease by a day or two; but it is very dirty, and mischievous if it salivate.

Collodion has also been used, but the results are not encouraging.

We will now sum up the precepts of treatment in a few words. Without denying that cases have happened, or may happen again, in which the sthenic excitement and plethora of the patient may induce the practitioner to draw blood moderately, it must be observed that the cases usually met with require a soothing, supporting, and tonic treatment.

In idiopathic erysipelas of the head, the patient must be confined to his room, if not his bed. If there is sickness, foul tongue, and evidence of a loaded state of bowels, he may have a cupful of warm chamomile tea for an emetic; a grain of calomel, and a little castor-oil or colocynth. If there is no such evidence, and the thing looks like a *blight* from cold, it is sufficient if the bowels be well opened. If there is pungent heat and thirst, and dry white tongue, the patient may quench his thirst with effervescing saline draughts, ginger-beer, oranges, and lemonade, and live on broth and slops. In other cases, with less strength, wine and soda-water, and beef-tea, fish, or puddings; and in others with a feeble pulse, stupor, dull colour of the eruption and decided signs of debility, port wine, or brandy, or (in the case of a Scotch or Irishman) whisky, with good beef-tea, and decoction of bark or quinine, with mineral acid. In most cases some soothing remedy at night is advisable to allay irritation and procure sleep. In the former set of cases, henbane with camphor mixture and Mindererus' spirit; in the graver cases, opium or morphia in sufficient doses.

In cases of simple erysipelas supervening on wounds, or after operations in hospitals, wine and tonics are indicated.

In simple erysipelas, the local applications should be such as make the patient feel more comfortable. The reviser used to see the warm poppy decoction used at Winchester with the best effect. In other cases the patient prefers bathing, with tepid soft water; in others, flour; in others, cotton wool. If the vesications break, an unguent of bismuth and glycerine is recommended. Of course, if there be any fair suspicion of suppuration, a knife should be thrust in.

In the phlegmonous erysipelas, at the beginning of shivering and other signs of fever, if there be signs that nature is tending to purify the blood by vomiting or purging of dark bile, an emetic and good dose of calomel with colocynth or castor-oil may be given first; always having respect to the use of these remedies, which is, not to follow routine, nor "lower the system," but to bring away fetid matters from the bowels. If they do this, they do good; if they bring away inoffensive mucus, they do harm. Then the patient's strength must be supported by good soup and wine, sleep be procured by opiates, and it were better to incise rashly, than to omit incision when needed. How different the fate of those Plymouth Dockyard patients (*C. 1.*) might have been if free incisions had been practised instead of such cruel and hopeless bleeding. At the commencement soothing applications should be made to any wound that is irritated. If discharges are fetid, whether from an original wound, or from the erysipelatous sloughs, they should be well deodorised, by solutions of chloride of lime, or by Condry's disinfectant, and by the application of bismuth and creosote ointment. The spread of chemical education amongst

the rising generation of surgeons may result in a saving of human life from these pestilential diseases. The incisions should not be permitted to bleed too much, and pressure with strips of lint dipped in turpentine may be used to restrain it if excessive. The *liquor cinchonæ cordifoliæ* of Battley, is, as the reviser believes, the best tonic, mixed with water acidulated with nitric acid. (See *ABSCESS Diffused.*)

In the cases of diffuse inflammation which arise as local manifestations of pyæmia, the treatment is the same. The reviser once experienced the effect of the *anatomical poison*; an inflamed finger, and intense general depression were the symptoms; old, hard, bright sparkling ale (which he cannot think of without gratitude) was the remedy. In the intense and well-marked cases of poisoning, as in puerperal fever, tonics and wine are required from the first. Wherever exudation takes place, hot fomentations should be applied, such as steaming bran poultices, sprinkled with camphorated spirits, to localise the malady, and incisions to give vent to the poison. It was well observed by Mr. Stafford, that in every case of dissection wound followed by diffuse inflammation, in which no incision was made, the result was fatal.

Respecting the use of leeches for the relief of pain in the axilla or side, in these cases, although they have the sanction of Sir A. Cooper, and although local depletion stands (as we show in art. *INFLAMMATION*) on a very different footing from general bloodletting, yet we cannot advise it. The results are not satisfactory; and hot fomentations to encourage suppuration are better. Contrary to the doctrine of the antiphlogistic school, it is a fact in these cases that gangrene is caused by a truly venomous state of the exudation, and not by mere violence of inflammation. (See *Dr. Graves's Clin. Med.* Dublin, 1843, p. 576.)

In the case of *metastasis*, stimulants, such as bran poultices, moistened with turpentine, may be applied to the part whence disease has receded, and hot brandy and water and other stimulants be freely supplied. Turpentine in purgative doses is greatly recommended by Dr. Copland, in this, and other apparently hopeless cases. Enemata of beef tea and brandy, as given by Dr. Todd, may also help to turn the scale.

Prevention.—Every case, not merely of erysipelas, but of offensive wound or fracture, should be isolated; great care should be taken that no effluvia can reach any bed, from closets or the like; bedding should be purified from time to time; the wards should be limewhited; floors should be scrubbed and not wetted; and above all, *sponges* should be abolished. No sponge used in any suspicious case should be used again; and the house-surgeons and dressers should deodorise their fingers by chloride of lime after dressing such cases. Moreover, operations should not be performed, nor accidents be admitted, during an epidemic of pyæmia or erysipelas. Patients can but die as they are.]

[*Erysipelas neonatorum.*—The erysipelas which attacks newly born children deserves a special notice, if only because it exhibits the causes and alliances of the disease generally, in their greatest perfection, and because the diminution in late years of mortality from this cause is an encouraging instance of the value of cleanliness and ventilation in extirpating disease.

It may occur within a very few days after birth,

and although it may affect almost any part of the body, the vicinity of the umbilicus is naturally the far most frequent seat. It soon spreads, especially to the genital organs and thighs, and produces vesication, suppuration in the subcutaneous tissue, and gangrene of the skin, if it be severe or phlegmonous. The constitutional symptoms are those of great debility, restlessness, whining, perhaps convulsions or coma. "The genital parts," say Drs. Maunsell and Evanson, "are not unfrequently destroyed altogether; and we have sometimes seen the scrotum become black and slough away, leaving the testicles bare and hanging loosely by the cords." So little, they add, spite of the intense mortality of the disease, are we justified in despairing of children under the most unfavourable circumstances, that we have seen a case recover after the whole scrotum and skin about the pubes had sloughed away, the bare testicles being again covered up by an extension and cicatrisation of the neighbouring integuments. (*Diseases of Children*, 4th ed. p. 223.)

Of the cause of this affection, all observers speak with one tongue. Foul air, especially hospital air. It attacks chiefly children born in lying-in hospitals, and comes, say Drs. Maunsell and Evanson, at periods when other malignant diseases, as diffuse inflammation, puerperal fever, scarlatina, &c. prove the *constitutio anni* to be of a typhoid character.

The treatment is that of erysipelas generally, modified to suit the age and feebleness of the patients. In the first place, as in all other cases, removal to a pure air is essential, and the utmost cleanliness of clothes and person. The navel should be dressed with an unguent of the nitrate of bismuth and glycerine, which will effectually absorb any putrid matter. Good breast milk should be supplemented by occasional teaspoonfuls of beef-tea and port wine and water. The practitioner may relieve the bowels by enema, and if he can do it without neglecting nourishment, may give tonics, of which the *liquor cinchonæ flavæ* of Battley, in the dose of a drop or two in sweetened water, is the best. Half-grain doses of quinine are recommended by many.]

[*ERYSIPELAS, Statistics of.*—The materials for this branch of our subject are either entirely wanting or very imperfect. The following brief notes may, however, be of interest.

The proportion which erysipelas bears to the total sickness of the whole population is unknown; but we may refer to the returns published by the metropolitan medical officers of health, during parts of the years 1857 and 1858. These returns were set on foot in the hope that they would prove a record of the *amount* of sickness, and of its *nature*, amongst that large part of the population which receives medical attendance gratuitously, whether from parishes, or from dispensaries, or within the walls of hospitals, and other charitable institutions. The project was abandoned at last, from the impossibility of obtaining the required information with sufficient regularity and completeness. But, from the returns that were published, it appears that during the last forty weeks of 1857, and the first forty of 1858, out of 791,506 cases of illness, there were 2649 of erysipelas. This is more than three times the number returned of cases of small-pox; and is nearly equal to the number of cases returned of acute pneumonia and pleurisy combined.

During the seven years 1848–54, the entire mortality, in England and Wales, from erysipelas was 14,950. There were thirty-eight other diseases more fatal. In 1855 the deaths were 2256.

In *London*, during the years 1844–58, 5768 deaths occurred from erysipelas, being at the rate of 384·4 per annum. The highest mortality was 579, in 1848; the lowest, 299, in 1857. Deaths from erysipelas are evidently not on the increase.

With regard to the *seasons*, Mr. P. H. Bird (in the pamphlet in which he gives a summary of his Jacksonian prize essay) says that 260 cases occurred in the following order:—

Spring, 66; summer, 49; autumn, 56; winter, 89. He quotes from the Registrar-General also, to show that during the years 1845–54, the total deaths in London were:—Spring, 1117; summer, 972; autumn, 875; winter, 1076.

Out of Mr. Bird's 260 cases, the deaths were 7·5 per cent. Dr. W. H. Stone (*Med. Times*, Nov. 12, 1859) states that the mortality of erysipelas in St. Thomas's Hospital is 7 per cent. Of 260 cases of erysipelas ambulans observed by Fenger, in the Frederick Hospital, at Copenhagen, 33 died, or 12·8 per cent.; of 194 cases of *erysipelas vulgaris*, there were 2 deaths; taking the 454 cases of both kinds together, the mortality is 7·7 per cent. Assuming 7 per cent. as the mortality, it is probable that, in 1857, there were 2100 cases of the disease in London.

Out of 217 of Fenger's cases, 198 arose within the hospital; 17 idiopathic, 200 traumatic. Of the 200 traumatic, 140 cases followed surgical operations. In this hospital, at Copenhagen, erysipelas seems, of late years, to have taken the place of hospital gangrene, which ravaged it previously. Puerperal fever has been prevalent throughout in the adjoining lying-in hospital.

The sexes, notwithstanding the greater liability of the male to traumatic diseases, die equally of erysipelas. In the seven years 1848–54, the males who died were 7464; the females, 7486.

Respecting the ages—

Males, under 1, 1725; 5, 2100; 5 to 15, 290; Females, „ 1, 1805; 5, 2363; 5 to 15, 278.

After these ages, the mortality in each sex is distributed pretty equally during each succeeding decenniad; but with an evident rise, as age increases. Between 55 and 65, 884 men, and 816 women died of erysipelas.] (*R. Druitt.*)

ERYTHEMA (from *ἐρυθρός*, red). A redness of any part. A mere rash or efflorescence, not accompanied by any swelling, vesication, or fever; circumstances which, according to Dr. Bateman, distinguish it from erysipelas. (*Synopsis of Cutaneous Diseases*, p. 119, ed. 3.) Its six varieties are described in the latter work. For the erythema mercuriale, see *Mercury*. The term is often wrongly applied to eruptions, attended with redness, and distinct papular and vesicular elevation, as we see in the instance of mercurial erythema, which Dr. Bateman says should be named *eczema*.

ESCHAR (from *ἐσχαρῶν*, to form a scab, or crust). This term is applied to a dry crust, formed by a portion of the solids deprived of life by the action of concentrated heat. When any living part

has been burnt by the actual or potential cautery, all that has been submitted to the action of this application, loses its sensibility and vital principle, becomes hard, rough on the surface, and of a black or grey colour, forming what is properly named an *eschar*, a slough, produced by caustics, or actual fire.

ESCHAROTICS (from *ἐσχαρῶω*, to form a crust over). Applications, which form an eschar, or deaden the surface on which they are put. By escharotics, however, surgeons commonly understand the milder kinds of caustics, such as the *hydrargyri nitrico-oxydum*, the nitrate of silver, subacetate of copper, &c.

EXÆRESIS (from *ἐξαίρῶ*, to remove). One of the divisions of surgery adopted by the old surgeons; the term implies the removal of parts.

EXCORIATION (from *excorio*, to take off the skin). A separation of the cuticle; a soreness, merely affecting the surface of the skin.

EXFOLIATION (from *exfolio*, to cast the leaf). The process by which a dead piece of bone is separated from the living is termed *exfoliation*. One part of a bone is never separated from another by the rotting of the dead part, for what comes away is as firm as it ever was. Before any part of a bone can be throne off by exfoliation, it must be dead. But, even then, till the process of exfoliation begins, the bone adheres as strongly as ever, and would remain for years, before it could be separated by putrefaction alone. A dead bone acts on the system, in the same manner as any other extraneous body. It stimulates the adjacent living parts, in consequence of which, such a process is begun, as must terminate in its being thrown off. The effects of this stimulus are, first, that the living adjacent bone becomes more vascular; a circumstance which always takes place when a part has more to do than is just sufficient for the support of life. Secondly, that the earth of the living part, when it is in contact with the dead bone, is absorbed; and there the bone becomes softer, and adheres by its animal matter only. As Mr. Wilson has stated, "before any mark of separation is seen on the surface, the living bone surrounding the dead, for the extent of a mere line, has become as soft as if it had been steeped in acid." (*On the Skeleton and Diseases of the Bone*, p. 281, 8vo. Lond. 1820.) Thirdly, that the living animal part is at last absorbed along the surface of contact: this part of the process commences, however, long before the removal of the earthy matter is finished; and both of these processes begin at the surface; though, in their course, they do not every where take place in an equal degree at the same time. Fourthly, in proportion to the waste made by this ulcerative absorption, granulations arise from the living surface, and fill up the intermediate space, so that there is no vacuum. These different stages together constitute ulceration. When any part of a bone is once loose, it is pushed to the surface in the same manner as most other inanimate bodies would be, and this stage is partly mechanical, and partly a continuation of ulceration. A proof of the third stage, above mentioned, may be derived from cases in which people die while exfoliation is going on. A small groove, or worm-eaten canal, can then be discovered, which becomes gradually deeper, and follows the irregularities of the living and dead surfaces. After the applica-

tion of the trepan, an annular piece of bone is frequently thrown off, which is always less than the space from which it came. This, as Mr. Hunter observed, would never be the case, were there not a loss of substance. However, in what manner this loss of substance is produced, has frequently been a question, many pathologists, and amongst them, I believe, is Mr. Gulliver, adopting the belief, that dead bone is not absorbed.

"Although (says Mr. Wilson) in general the absorption takes place in the living bone, it still appears, that, under peculiar circumstances, the absorbing vessels have the power of acting on and removing the substance of dead bone. This happens after the dead part has been separated from the living, and when, from its shape, and the form of the living surrounding bone, it is prevented from obtaining a passage to the surface of the body; as in exfoliations of the cranium, when the inner table of the exfoliated part is broader and wider than the outer table." (*On the Skeleton*, &c. p. 282.) In very hard bones, the colour of the dead exfoliating portion is generally white; but, in softer bones, it is yellow, dark, and sometimes black. (*Wilson*, op. cit.)

It was anciently believed, that whenever a bone was denuded, the exposed surface must necessarily exfoliate; and this being taken for granted, the old surgeons used to put immediately in practice whatever they thought best calculated to bring on an exfoliation as quickly as possible. For this purpose, the actual cautery was usually applied to the part of the bone, which was uncovered; and as, under such treatment, a portion of the bone was of course killed, and then exfoliated, the prejudiced practitioner believed, that he had only accelerated a process, which must of necessity have followed in a more slow and tedious manner.

According to Mr. Hunter, neither caustics nor the actual cautery hasten exfoliation; they only produce death in a part of the bone, which is the first step towards exfoliation; and if they ever hasten exfoliation, when the bone is already dead it must be by producing inflammation in the adjacent living bone; a change that makes it exert a power of which it was previously incapable.

Exfoliation is not a necessary consequence of a bone being laid bare, and deprived of its periosteum. If the bone be in other respects uninjured, healthy, and enjoy a vigorous circulation of blood through its texture, granulations will be generated on the surface of such bone, and they will cover and firmly adhere to it, without the smallest exfoliation being thrown off; especially in young subjects. But, if caustic, stimulating, or drying applications be made use of, or the bone be left for a considerable time exposed, the circulation in the superficial portion of it will necessarily be disturbed and destroyed, and that part of the surface, through which the circulation ceases to be carried on, will be separated, and cast off, by the process of exfoliation.

If any application to an exfoliating portion of bone be at all efficacious, it must be one which will stop the mortification in the affected bone, and promote the absorption of those particles of phosphate of lime, which form the connection between that which is living and that which is actually dead. And as the bone dies from the same causes as the soft parts mortify, we should at least follow in practice the same principles which we adopt in

the latter instance ; and though, from the inferior vascularity and vital power of bones, we cannot expect surgery to have as much control over their affections, as over those of the soft parts, yet, every good will thus be obtained, which it is possible to acquire. Attention to such principles will at least teach us to refrain from making the death of part of a bone more extensive than it would be, if the cautery, caustics, and strong astringents were not employed.

The best mode of attempting to prevent an exfoliation from occurring at all in a bone, that has been exposed by a wound, is, to cover the part again, as soon as possible, with the flesh, which has been detached from it. This, as I shall hereafter notice, (see HEAD, INJURIES OF,) may generally be practised with advantage, when the scalp has been detached from the cranium, provided the flap still retain even the most limited connection with the rest of the integuments.

When the exposed bone cannot be covered, it should be dressed with the mildest and simplest applications, with plain lint, or lint spread with the unguentum cetacei.

The dead pieces of bone, when very tedious in exfoliating, when wedged in the substance of the surrounding living bone, and when so situated as to admit of being safely sawn, or cut away, may sometimes be advantageously removed in this manner. (See CARIES and NECROSIS.) In such operations, bone nippers, elevators, or Hey's saws may be employed with great convenience ; and where these are not applicable, the saw invented by Machell, and described in Sir A. Cooper's *Surgical Essays*, or another devised by Graefe, and explained by Schwalb (*De Serra Orbiculari*, 4to. Berol. 1819), deserve to be recollected.

Tenon published three Memoirs on Exfoliation. The two first are inserted at pages 372 and 403 Mem. de l'Acad. des Sciences, 1758 ; the third at p. 223 of the same work, for 1760. P. Poissonier, An recenti vulnere nudatis ossibus exfoliatis? conclusio negans, 4to. Parisii, 1760. Journ. de Méd. par Le Roux, t. xxxi. p. 801 ; t. xxxii. p. 181 ; t. xxxiii. p. 168 ; t. xxxvi. p. 537 ; t. xxxviii. p. 153 ; t. xxxix. p. 132. Theden, Neue Bemerkungen, &c. kap. 3, 8vo. Berlin, 1782. EXOMPHALOS (from ἐξ, out of, and ὀμφαλός, the navel). A hernia at or near the navel.

EXOPHTHALMIA (from ἐξ, out, and ὀφθαλμός, the eye). In *exophthalmia*, *ophthalmoptosis*, *ptosis bulbi oculi*, the eyeball is of its natural size, and free from disease ; it merely changes its situation, and partly or completely protrudes from the orbit. It is only confusing the subject to consider, as specimens of this disease, the cases in which the globe of the eye is affected with enlargement, and, on that account, projects from the orbit in a preternatural degree, as happens in hydrophthalmia, staphyloma, and cancerous disease. When the globe is pushed entirely out of the orbit, it generally lies upon the temple or cheek, and vision is totally destroyed. There are instances, however, in which a considerable degree of sight was recovered, notwith-

standing the exophthalmia was complete, and had lasted several years. (*Hope, in Phil. Trans. for 1744. Richter's Bibl. bd. 4, p. 343.*)

There are three descriptions of causes which may occasion exophthalmia :

1. The first and least common is a violent concussion of the head. A man fell from a height of about fifteen or sixteen feet, and pitched upon his head. The right eye was forced out of its socket, and hung over the cheek. The patient was deprived of his senses immediately after the accident, and affected with coma. There was a contusion over the right parietal bone ; but no fracture. The eye spontaneously resumed its natural position a short time after the accident, and, in the course of a month, with the assistance of low diet and repeated bleeding, the cure was completed. (*Mém. de l'Acad. de Chirurgie, t. 1, p. 198, 4to.*) It is alleged that the eye has been forced out of the orbit in a violent fit of sneezing. But such cases must be very uncommon, and imply a considerable relaxation of those parts which serve to retain the eye in its socket, or some other predisposing causes, to which attention should be paid in the treatment. (*Richter, Anfangsgr. der Wundarz. bd. iii. p. 407, ed. 1795.*)

2. A far more frequent cause of exophthalmia is a thrust in the eye with an instrument, which is narrow enough to pass between the orbit and the eyeball, so as to push the latter out of its place. A stick, a tobacco-pipe (*White's Cases in Surgery, p. 131*), a foil, &c. may cause the accident. Repeated experience proves, that, in such cases, though the optic nerve and muscles of the eye may be forcibly stretched, the interior parts of the organ seriously injured, and the dislocated eye generally deprived of the faculty of seeing, yet, when the organ is replaced as speedily as possible, it not only sometimes recovers its natural motion, but also its original power of vision. (See *Scultet. Appendix, obs. 69. Covillard, obs. 27. Borellus, centur. 3 obs. 54. Rhodius, centur. 1 obs. 84. White's Cases, p. 131.*) Previously to reducing the eye, we should examine the instrument which was pushed into the orbit ; as, when it is brittle, a fragment of it may remain behind in the socket, and require to be extracted by means of the finger or a probe. When the weapon is pointed or hard, it sometimes pierces the bones of the orbit, and enters the brain, nose, or antrum. In the first case, which is often difficult to ascertain immediately, though after a time, it is generally rendered plain enough by the symptoms induced, the consequences are mostly fatal. In the two other cases, although the danger is not pressing, the surgeon should be very attentive, in the event of suppuration, to procure and maintain a ready outlet for the matter.

There is generally little difficulty in replacing the eye. Frequently it returns of itself into its natural situation, as soon as any trivial obstacles to its reduction are removed ; and in other instances, it easily admits of being put into its proper place with the hand. The indication, says Richter, is always accomplished with more facility the sooner it is attempted. When the protrusion has existed several days, and the eye and other parts in the orbit are already inflamed, Richter recommends us to endeavour to diminish the inflammation by general antiphlogistic means, and

external emollient applications, before we try to replace the eye, and the reduction of this organ is afterwards to be effected in a gradual manner. When the optic nerve, and one or more of the muscles of the eye are torn, no hope can be entertained that the eyesight and motion of the organ will ever be regained. But this degree of injury, as Richter observes, cannot always be immediately detected, because the optic nerve and muscles are concealed by the conjunctiva; and, if the nature of the case were known, still it would be advisable to replace the eyeball.

When the instrument with which the eye has been pushed out of its socket is blunt and thick, like a finger, a stick, a foil, &c. the eyeball itself always sustains a violent contusion, which brings on vehement inflammation, and lessens or destroys all hope that, after the reduction, the eyesight will be restored. Sometimes an extravasation of blood in the orbit occurs, the iris is lacerated, the cornea burst, and a part of the humours of the eye discharged. Although, under such circumstances, it is scarcely to be expected that the eyesight can be recovered, yet, it is proper to reduce the eye, because, should the organ be destroyed by suppuration, or the loss of its humours, the deformity may be obviated by an artificial eye, which is not the case when the eye has been cut away. It is also to be considered, that the mischief often seems to be worse than it really is, and the eyesight is sometimes regained, contrary to all expectation.

After the reduction of the eye, the first care of the surgeon should be to prevent and diminish inflammation. In some cases, the inflammation is slight; while, in others, especially when the eyeball has been severely struck, it is extremely violent. All the usual antiphlogistic means, both general and topical, are to be employed, and, of the latter, Richter says, astringents are the best, as the inflammation arises from the contusion and stretching which the parts have suffered. The possible consequences of inflammation, such as suppuration, opacity of the cornea, &c. are to be treated according to the rules laid down in other parts of this dictionary. (See CORNEA, OPACITY OF; HYPOPIUM; OPHTHALMIA.) In general, the sight is restored in proportion as the inflammation is diminished. Should this not happen, after the exophthalmia has been entirely removed, the surgeon must try what effect such remedies as stimulate the nerves will have upon the optic nerve.

3. The third cause of exophthalmia is a preternatural tumor in the orbit or neighbouring parts. The swelling, as it enlarges, gradually pushes the eyeball out of its socket. The tumors, which may be formed in the orbit, are of several kinds. The principal, however, are encysted swellings, which contain either fat, an aqueous fluid, a pappy substance, or a thick matter. Sometimes, the cellular tissue in the orbit is affected with induration and swelling, so as to force the eye partly or completely out of this cavity.

Adipose swellings occupy the interspace of the recti muscles, emerge between the globe and the orbital circumference, and have an oblong figure. When the conjunctiva is freely divided, the fatty mass is easily drawn forwards with a hook, and dissected out. (Travers, in *Synopsis of Dis. of the Eye*, p. 225.)

An abscess in the orbit may cause a protrusion

of the eyeball. (Pellier.) Exostoses may have the same effect. Sir Astley Cooper has related one case, which proved fatal, in consequence of the exostosis making its way to the brain through the orbital plate of the os frontis. (*Surgical Essays*, part i. p. 157.) Mr. Guthrie has seen two instances: in one, the disease attained the size of a large marble, and then became stationary; in the other, it was much larger, and a portion of it had been ineffectually removed by means of a hot iron, which increased the inconvenience, without giving any relief. Hence, if an operation were deemed advisable, Mr. Guthrie would prefer the cautious use of a small chisel or saw. (*Operative Surgery of the Eye*, p. 154.) This author is at the same time aware of the case, in which M. Brossaut brought about the exfoliation of a considerable part of an exostosis of the os planum and internal angular process with caustic, so that the eye returned into its place, and the cure was completed. (*Mém. de l'Acad. de Chir.* t. v. p. 171, 4to.) In the records of surgery may be found examples, in which the displacement of the eye was produced by a tumor that grew out of the frontal sinus. (See *Langenbeck's Neue Bibl.* bd. ii. p. 247.) In some cases, in consequence of suppuration in the antrum, the lower part of the orbit is raised, and the eye forced out of its place. Fungous diseases of the antrum may occasion the same mischief. (See *Parisian Chir. Journal*, vol. i. p. 104, &c.)

Schmidt records two cases of exophthalmia, produced by an hydatid of the lachrymal gland. One had a fatal termination; but, in the other, a puncture gave vent to an ounce of clear fluid, and cured the protrusion of the eye; but the eyesight was lost. (*Ueber die Krankheiten des Thränenorgans*, p. 54. Farther particulars of the latter case may be seen in Mr. Guthrie's work, p. 157.)

Not long ago, Langenbeck extracted from the frontal sinus of a girl, a large hydatid, which had forced the outer table considerably forwards, and depressed the orbital plate of the os frontis so far, that the eyeball was propelled as low as the extremity of the nose. After the front of the sinus had been perforated, and the hydatid removed, there was a cavity left two inches and a half in depth. (*Neue Bibl.* b. ii. p. 247, Hanover, 1819.) My friend Mr. Lawrence mentioned to me a remarkable case, which presented itself at the London Eye Infirmary: it was an exophthalmia, which arose from a collection of hydatids in the orbit, and was cured by making an incision, and afterwards promoting their discharge. In all these examples, the eyeball is displaced from the orbit gradually, and vision is at length impeded. Instances, however, are on record, where the sight was never lost, though the eye was protruded for years. (See *Richter's Chirurg. Bibliothek*, bd. iv. st. ii. p. 243. *White's Cases in Surgery*, p. 135.) In one instance, the sight was not at all lessened, and the iris retained its natural mobility. (*Langenbeck, Neue Bibl.* bd. ii. p. 245.)

Experience proves, also, that after the reduction, the motion of the eye and power of seeing may be regained in cases where the eye has been gradually pushed out of the orbit, and been displaced a considerable time, even as long as several years, during all which period vision was lost. (*Acrell, Brocklesby, in Med. Obs. and Inquiries*, vol. iv. p. 371.) Langenbeck relates a case of exophthalmia

from a steatoma in the orbit, where, though vision was entirely prevented during the displacement, the pupil was of its regular shape, and the iris capable of motion: after the extirpation of the tumor, the eyesight became so good, that the patient could discern the smallest objects. (*Neue Bibl.* bd. ii. p. 240.) In order to reduce the eye into its natural position, it is necessary to remove the cause by which its protrusion is occasioned. Suppuration and fungous tumors in the antrum must be treated according to directions laid down in the article ANTRUM. The induration and swelling of the cellular substance in the orbit may be sometimes dispersed by means of mercury. (*Louis, sur Plusieurs Maladies du Globe de l'Œil, in Mém. de l'Acad. Royale de Chirurgie, t. xiii. éd. 12mo.*) When such treatment fails, we are recommended to extirpate the eye. (*Richter, Anfangsgr. der Wundarzn, bd. iii. p. 413.*) Exostoses, situated in the anterior part of the orbit, may sometimes be removed. The continental surgeons generally advise us to expose the tumor by an incision, and to apply caustic or the actual cautery to it, in order to kill the protuberant part of the bone, and make it exfoliate. In this country, most practitioners would prefer the employment of cutting instruments for removing such exostoses. When, however, the tumor lies deeply in the orbit, if it cannot be got at, and it should resist the effect of mercurial and other medicines, we are directed to extirpate the eye. (*Richter, op. et loco cit.*) Abscesses in the orbit ought to be opened, and after this has been done, the eye generally returns into its proper position. (*Pellier.*) When encysted tumors in the orbit admit of being extirpated in the customary manner, the plan should be adopted; but, when this cannot be done, Richter's advice may be followed, which is to open them, press out the contained matter, and afterwards extract the cyst. Considerable difficulty, however, frequently attends every effort to remove the whole cyst, and unless this be done, a permanent cicatrization cannot be expected. (See *Travers's Synopsis*, p. 225. See TUMORS, ENCYSTED.)

On account of the vicinity of the brain, and the communication between the parts within the orbit, and the dura mater, the extirpation of tumors from that cavity is not exempt from risk of fatal consequences, as two cases, published by Langenbeck, fully prove. (*Neue Bibl.* bd. ii. pp. 241—244.) I remember a young lady who was referred to Mr. Lawrence and myself, by Mr. Maul of Southampton, for advice respecting a tumor, occupying the inner and upper portion of the orbit, and attended with a degree of exophthalmia, constant exacerbation at the period of the menses, and occasionally double vision. (See DIPLOPIA.) We refrained from advising any immediate attempt at extirpation, the swelling being so firm and immovable, that the disease was suspected to be partly of a bony nature. However, on seeing this case, about a fortnight afterwards, I was surprised to find the tumor not more than half its former size, and all the firm and (what was conceived to be) bony induration below the superciliary ridge of the os frontis gone, as well as the exophthalmia, and derangement of vision. Some sharp bony irregularities, however, could now be most plainly felt, projecting in front of the diminished swelling.

A memorable case of exophthalmia is related by Mr. Travers: the globe of the eye appears to have been gradually forced upwards and outwards, and

to have had its motions considerably impeded, in consequence of the orbit being partly occupied by two swellings, which were of the nature of aneurism by anastomosis. (See ANEURISM.) The swellings could not have been removed, without at the same time extirpating the eye. Mr. Travers was therefore induced to try whether applying a ligature to the carotid artery would have the effect of checking and curing the disease; an expectation which was warranted by analogous instances, in which the growth of swellings, and their dispersion, are brought about by lessening the quantity of blood determined to them. The experiment completely succeeded; the swellings in the vicinity of the eye subsided; the patient was freed from several grievous complaints, to which she had been previously subject; and, amongst other benefits, a cure of the exophthalmia was one result, which most interests us in the present place. The case is also highly important on other accounts, and, more particularly as confirming the fact, that the carotid artery may be tied, without any dangerous effects on the brain, and as proving, that, in cases of aneurism, the surgeon should not be afraid of proceeding to such an operation. (See *Med. Chir. Trans.* vol. ii. art. 1.) The judgment and decision with which Mr. Travers acted in this case, appear to me highly meritorious.

The carotid artery was also tied by Mr. Dalrymple, of Norwich, in a case very similar to the preceding, and with equal success. (See *Med. Chir. Trans.* vol. vii. p. 111, &c.)

Mr. Guthrie has seen an exophthalmia on each side, the result of an aneurism of each ophthalmic artery, and other disease in the orbits. (*Operative Surgery of the Eye*, p. 158.)

When the causes of exophthalmia have been removed, the eye must be put into its natural situation. If the organ has been long displaced, the surgeon often finds the fulfilment of this indication attended with difficulty. Indeed, he is frequently obliged to employ methodical bandages for the purpose of promoting the gradual return of the eye into the orbit. Yet, even in such cases, the eyesight is often regained: but, if this should not happen spontaneously, stimulants and tonics are to be applied.

[Mr. Poland, in a paper published in the *Ophthalmic Hospital Reports*, October 1857, gives the most recent systematic view of the causes of protrusion of the eyeball.

1. *Congenital*.—*a.* Real protrusion; *b.* Apparent from shortening of levator palpebræ and lids.

2. *In the eye itself*.—*a.* Inflammation of the globe, ophthalmitis; *b.* Phlebitic ophthalmitis; *c.* Hydrophthalmos; *d.* Tumors (1. Scrofulous; 2. Encephaloid; 3. Melanotic; 4. Osseous degeneration; 5. Hydatid).

3. *Within orbit*.—*a.* Inflammation of cellular tissue, idiopathic and traumatic; *b.* Suppuration and abscess; *c.* Erysipelatous and phlegmonous inflammation; *d.* Foreign bodies; *e.* Excess of development of fat; *f.* Tumors (1. Encysted; 2. Hydatid; 3. Encephaloid; 4. Osseous); *h.* Aneurism and effusions of blood; *i.* Venous congestion; *k.* Paralysis of muscles of eyeball—ophthalmoplegia; *l.* Spasm of muscles of eyeball, as in tetanus.

4. *External to orbit*.—*a.* Above: nodes, hydrocephalus, fungus of dura mata, polypi in frontal cells and diseases thereof, tumors of brain; *b.* Below: diseases of the antrum; *c.* Internal: nasal

polypi and tumors; *d.* External: exostosis; *e.* In front: contraction of lids and eye slipping through—hernia oculi.] (*C. Bader.*)

EXOSTOSIS (from ἐξ, out, and ὀστέον, a bone). An exostosis is a tumor formed by an exuberant growth of bony matter on the surface of a bone, or it is formed by the more or less considerable enlargement of a part, or the whole, of a bone. (*Boyer, Mal. Chir.* t. iii. p. 541.)

In general, however, it is only when the enlargement is partial that it is termed an exostosis. As Mr. Mayo has pointed out, some hypertrophies of bone are connected with a salutary principle; while others constitute curable, or incurable diseases. The arm of a blacksmith acquires, through daily exertion, additional muscular force, weight, and size; the bones in it enlarge; their crust becomes harder, and of a more compact grain; and the lines upon the surface, which give attachment to tendons, become rough and prominent ridges. This is health. When Mr. Cheshire's apparatus for supporting the spine is worn, the pressure on the lower jaw generally causes this bone to enlarge, and to throw out a bony swelling, where the chin strap is applied. This tumor is an exostosis, yet it evidently results from the salutary principle, which strengthens a part in proportion to the exertion imposed upon it. (See *Mayo's Outlines of Human Pathology*, p. 11.)

While the growth of the whole body is proceeding rapidly, abnormal swellings of parts of bones are common, especially of the clavicle, sternum, or ribs. These are exostoses, which require no treatment, as they generally subside of themselves in the course of a year or two. Exostoses are still more common at the period when the body has recently attained its full growth. But the disease is not limited to the early, nor to the middle periods of life. (*Ib.*)

One division of exostoses is into *true* and *false*; the former being of a truly osseous consistence, the others being more or less hollow, spongy expansions of the bones, sometimes containing a quantity of cartilaginous, fibrous, medullary, or fungous matter within the shell of the disease. Periostoses, or mere thickenings of the periosteum, are also sometimes classed amongst *false* exostoses. (*Dict. des Sciences Méd.* t. xiv. p. 218.) According to Sir Astley Cooper, exostoses have two different seats: by *periosteal* exostoses he means an osseous deposition seated between the external surface of

the bone, and the internal surface of the periosteum, and firmly adherent to both; by *medullary* exostoses, he signifies a similar formation, originating in the medullary membrane and cancellated structure of a bone. The same experienced surgeon makes two other general divisions of exostoses into the *cartilaginous* and *fungous*, the first being "preceded by the formation of cartilage, which forms the nidus for the ossific deposit," while the second is a tumor softer than cartilage, yet firmer than fungus, in other parts of the body, containing spicula of bone, being of a malignant nature, and depending "upon a peculiar state of constitution and action of vessels." It is a disease similar to "fungus hæmatodes, but somewhat modified by the structure of the part in which it originates." (*Surgical Essays*, part i. p. 155.)

If a true exostosis be immersed in diluted muriatic acid, so as to separate the earthy part of it, the tumor will yet retain its form, and present the same kind of fibro-cartilaginous matrix which exists in healthy bone. (*Ib.*)

[Rokitansky arranges the non-malignant outgrowths of bone under two heads—1. Exostoses, which he subdivides into the compact (*osteosclerosis*) and the porous (*osteoporosis*); the former consists of the hard ivory exostoses, the latter comprises the remainder of the simple bony outgrowths, whatever their form or the arrangement of the osseous or cartilaginous tissue composing them may be; that is to say, whether their cancellated interior be more or less open, whether they possess a medullary canal or not, whether they originated as bony or cartilaginous growths, and whether the cartilage, when present, was central or cortical in position. 2. Osteophytes. Under this term he ranges all those numerous deposits or bone resulting from simple or specific inflammatory action. These he designates according to the various appearances they assume—the villous osteophyte, the laminated, the warty or stalactitic, the thorny or styloid, and one which resembles drops or small streams of osseous matter. He excludes from this classification the bony bases, internal skeletons, or capsules of the several morbid growths occasionally invading the osseous tissue, such as are found in enchondroma, osteosarcoma, cancer, &c.]

M. Nélaton divides all non-malignant exostoses into the osseous and the osteo-cartilaginous. Under the first head he includes ivory exostoses, as well as all purely bony growths. Under the second he ranges all exostoses in which cartilage is found blended with bony tissue. Of these he makes two varieties, one in which the cartilage forms a cortex to the osseous growth; a second, in which the cartilage will be found in the centre of the bony mass. The general enlargement of the whole shaft of a cylindrical bone, or the general thickening of the cranial bones, he describes under name of hyperostosis or hypertrophy. The malignant growths of bone he separates entirely from exostoses, and describes under their appropriate forms of cancerous disease.

Osseous and osteo-cartilaginous exostoses are found to possess the same chemical constituents and in the same proportions as in normal bone or cartilage. Their microscopical appearances are also identical. The ivory exostoses, however, form an exception in some degree to these remarks. Nélaton gives from Berzelius the follow-

ing comparative analysis of sound bone and of ivory exostoses :—

	Bony exostoses or sound bone.	Ivory exostoses.
Animal matter	33.30	28.57
Phosphate of lime, of magnesia, &c.	54.20	68.88
Carbonate of lime, alkaline, chlorides, &c.	12.50	2.00
Loss	00.00	00.55
	100.00	100.00

(Nélaton, *Éléments de Pathologie Chirurgicale*, tom. ii. p. 3.)

The microscopical characters also in the ivory exostoses are less distinct and more irregular than in ordinary bone. According to Rokitsansky, "the Haversian canals are small and far apart, and many of them are surrounded by a distinct and completely defined (völligabgeschlossenen) lamellar system. With regard to the corpuscles, we find large tracts without any of them, while at other spots they are clustered together in dense groups."—(*Manual of Pathological Anatomy*, by Rokitsansky, translated for the Sydenham Society by C. H. Moore, vol. ii. p. 127.)

In describing a particular specimen of ivory exostosis, Mr. Paget says (*Lectures on Surgical Pathology*, vol. ii. p. 236), "in the hardest parts there are neither Haversian canals nor lacunæ; in the less hard parts the canals are very large, and the lacunæ are not arranged in circles around them, and everywhere the lacunæ are of irregular and distorted forms."]

Exostoses differ in size. Those of the cranium are generally small and circumscribed, yet exceptions occur; for Sir Everard Home removed a very large tumor, which had a bony base, and was situated on the head. (Sir A. Cooper, *Surgical Essays*, part. i. p. 156.) The largest true exostoses are formed upon the long bones. In the history of surgery may be found numerous cases of enormous exostoses; but nearly all of them of the species termed *false*, and many of them were situated on the jaw, the clavicle, or the extremities of the long bones. Observations of this kind are abundant in l'Histoire de l'Acad. des Sciences; les Mém. de l'Acad. de Chir.; the Sepulchretum Anatomicum; the writings of Morgagni, &c. (*Dict. des Sciences Méd.* t. xiv. p. 219.)

The bones most frequently affected with exostosis are those of the cranium, the lower jaw, sternum, humerus, radius, ulna, bones of the carpus, and particularly the femur and tibia. There is, however, no bone of the body which may not become the seat of this disease. It is not uncommon to find all the bones of the cranium affected with exostosis, or, rather, hypertrophia, and the ossa parietalia sometimes an inch thick.

The exostosis which forms between the outer table of the skull and the pericranium, is of extremely hard consistence, and generally attended with little pain, while the *fungous* exostosis, springing from the diploe of the skull, is less firm, more vascular, and of a malignant nature, making its way through the inner table, and occasioning disease of the dura mater, and fatal effects on the brain. (See DURA MATER.)

Sometimes an exostosis is confined to a small part of the affected bone, composing a mass su-

peradded to its surface, and of various shapes. Sometimes it rises insensibly, having no very distinct limits, and resembling a more or less regular portion of a sphere. In some instances its figure is styloid, and it projects in a greater or less degree. On other occasions its base is rendered distinct by a pedicle, or contraction, which varies in breadth and length in different cases. In particular instances, evidently resulting from inflammatory action, the exostosis, or rather osseous enlargement, though limited to the surface of a bone, occupies the whole extent of it. Thus the external surface of one of the bones of the skull has been found occupied by an exostosis, while the inner table was in the natural state. The whole circumference of the femur sometimes acquires an enormous size, at the same time that the medullary surface continues entirely unchanged. These are the *periosteal* exostoses of Sir Astley Cooper. In other examples, on the contrary, the two surfaces and the whole thickness of the bone are deformed by an augmentation of bulk; and when this happens in a cylindrical bone, the medullary cavity is more or less reduced, or even totally obliterated. In a few extremely uncommon cases, the substance of a bone acquires great solidity (osteosclerosis), and a hardness compared to that of ivory, without any material increase of bulk. An exostosis sometimes, though rarely, occupies the whole extent and thickness of a bone; but when this happens in a cylindrical bone, the articular surfaces generally remain in their natural state.

Common situations of exostoses are the upper part of the humerus and tibia, and the lower part of the femur, especially near the insertion of the tendon of the adductor magnus. (Sir A. Cooper.) In the long bones exostoses are generally narrow, and of greater height than thickness; sometimes largest at their base, sometimes the reverse. In the flat bones they are usually broad, but they form flat discs, connected to such bones by means of short narrow pedicles. In the round bones they are rounded and nodular. To these laws, as Mr. Mayo observes, there are many exceptions. (*Outlines of Human Pathology*, p. 12.)

The structure and consistence of exostoses present great differences. Sometimes, especially when the tumor is not very large, and situated on the surface of a cylindrical bone, one may trace with the eye the diverging of the osseous fibres, in the interspaces of which we might say that there is deposited a new bony substance, the organisation of which is less distinct. Sometimes the tumor is entirely cellular, and formed of a few broad laminae, intercepting extensive spaces, which are filled with matter different from the medulla, and of various quality. This case is denominated the *laminated exostosis*. Sometimes the enlarged portion of bone makes a sort of hollow sphere, with thick hard walls, and the cavity is filled with a firm indolent fibrous substance. One form of exostosis Sir Astley Cooper has named the *cartilaginous exostosis of the medullary membrane*. "In this case, the shell of the bone becomes extremely expanded, or rather the original shell is absorbed, and a new one deposited; and within this ossified cavity thus produced, a very large mass of cartilage is formed, elastic, firm, and fibrous." It is not malignant, but often ends in a very extensive disease. (*Surgical Essays*, part i. p. 173.)

In other instances the tumor is perfectly solid, exceeding in consistence that of the hardest bones, and equalling that of ivory. The ivory exostosis is thought by Mr. Mayo to be occasionally malignant; and he mentions that Mr. Stanley has a preparation of one, which is combined with medullary sarcoma. (*Human Pathology*, p. 14.) I suspect that this must have been an accidental concurrence with the more solid exostosis. Here the surface is sometimes smooth, and like that of the bone in its natural state; sometimes irregular, full of little projections, and in some degree stalactical. It is uncommon to find a large portion of an exostosis converted into a pultaceous substance; but it is not at all unfrequent to see this substance composing part of the tumor. Lastly, it often happens that the same exostosis presents an assemblage of the ivory substance, and of the cellular laminated substance, the cavities of which are partly filled with a pultaceous matter, and partly with a sort of gelatinous substance.

An extraordinary instance of what is sometimes called *spiculated* exostosis, is related. Laminae, or ramifications of bone, are represented as projecting from the various bones, and causing ankylosis of every joint, with the exception of the wrists and knees. One branch is seen to extend from the coccyx to the femur. Another case is also reported by Freke, where the exostoses are compared to the branching of coral, the bony formations projecting from the cervical and other vertebræ, and joining others from the ribs, so as to make a kind of bodice on the back. (See *Phil. Trans.* vol. 41; and *Wickham, On Diseases of Joints*, p. 8.)

When an exostosis is not very large, it hardly affects the surrounding soft parts; but when it has made considerable progress, the muscles become stretched and emaciated, the cellular tissue is thickened, and, its layers being adherent together, a kind of confusion is produced amongst all the adjacent parts. Exostoses not of considerable size may, however, seriously interrupt the functions of certain organs. The action of the flexor muscles of the leg has been known to be obstructed by an exostosis in the vicinity of the knee. An osseous tumor, arising near the symphysis pubis, need not be very large to impede considerably the functions of the urethra, as experience has proved. An exostosis in the orbit has been known to displace the eye and destroy vision. Lastly, exostoses, when situated near certain important organs, and of large size, may affect with different degrees of gravity the functions of these parts, as the brain, the lungs, &c. (See *Boyer, Mal. Chir.* t. iii. p. 541—544.)

Sir Astley Cooper has related a case, in which the eyes were pushed out of their sockets by two exostoses, which grew from the antra, and one of which destroyed the patient by making its way to the brain through the orbital process of the os frontis. (*Surgical Essays*, part i. p. 157.) In one instance, reported by the same author, an exostosis from the sixth or seventh cervical vertebra abolished the pulse at the wrist, by pressing upon the subclavian artery (p. 159). In another, a *cartilaginous* exostosis of the medullary membrane of the lower jaw extended so far back that it pressed the epiglottis down upon the rima glottidis, and caused such difficulty of respiration, and so much irritation, that the patient was destroyed (p. 175).

[Mr. Paget refers to an enormous specimen of exostosis in the Museum of the College of Surgeons. It formed an irregular oval mass surrounding the upper two-thirds of the tibia. It was composed of cancellous structure, surrounded by a thin layer of compact tissue. It measured exactly a yard in circumference, and the limb, after amputation, weighed forty-two pounds. He also refers to a very extensive and fine specimen of ivory exostosis in the Museum of the University of Cambridge, of which he gives a wood-cut (p. 236, op. cit.) The disease appears to occupy the os-frontis, all the bones of the face, and to encroach considerably on the interior of the skull. (*Lectures on Surgical Pathology*, vol. ii. p. 233.)]

Some particulars of an exostosis are recorded which projected from the posterior surface of the symphysis pubis into the bladder. The case, while the patient lived, might have been mistaken for an adherent calculus. (See *J. Cloquet, Pathol. Chir.* p. 130, 4to. Paris, 1831.) Dupuytren had a case in which an exostosis of the femur obliterated the femoral artery. (See *Clin. Chir.*) A patient had an exostosis of the first rib, which threw forward the subclavian artery, so as to give the appearance of a subclavian aneurism. (See *Mayo's Outlines of Human Pathology*, p. 12.) I find a case referred to, in which an exostosis of the anterior surface of the sacrum pushed the rectum so far forwards as to render the introduction of a small bougie into that bowel very difficult. (*B. Bell, On Diseases of Bones*, p. 115, 12mo. Edinb. 1828.) Frequently exostoses interrupt the free movement of a joint; thus, Mr. H. Lyford removed one which was of the size and shape of the little finger, and situated just on the inside of the capsular ligament of the shoulder joint, on the front and inner part of the humerus. The direction of the point was upward and inward toward the clavicle and sternum, and the motion of the humerus inwards was interfered with. (See *W. J. Wickham, On Diseases of the Joints*, p. 7.)

Venereal exostoses, or nodes, are observed to arise chiefly on compact bones, and such of these as are superficially covered with soft parts, as, for instance, the bones of the cranium, and the front surface of the tibia, the sternum, the anterior part of the clavicle, the outer surface of the radius just above the wrist, the back part of the ulna just below the elbow.

The causes of exostoses are obscure. They may be induced, however, by a blow, or by pressure. Most writers impute the disease to internal causes, such as scrofula and lues venerea. That the latter affection is the cause of nodes, which are certainly a species of exostosis, no one will deny: but that scrofula is concerned in producing exostoses is more doubtful. Sometimes I have suspected that some of those bony swellings, which are so common in children during the rapid growth of the body, are connected with a scrofulous constitution. At all events, I have noticed them with great frequency in children of this description, though it might only be an accidental coincidence.

The readiness with which bony tumors form in some persons, renders it probable that constitutional causes have great influence. Thus, such a blow as, in the generality of persons, would hardly excite notice, will in others bring on swellings of the bone which is struck. Sir Astley Cooper adverts to a young friend of his, in whom an exostosis,

which was undoubtedly caused by a blow, is growing on the metacarpal bone of the little finger. (*Loc. cit.*) Mr. Abernethy used to mention in his Lectures, the case of a boy, from Cornwall, who was so excessively afflicted with an apparent predisposition to exostoses, or an exuberant deposition of bony matter, that a very trifling blow would occasion a bony swelling on any bone of his body. His ligamentum nuchæ was ossified, and prevented the motion of his neck; the margins of his axillæ were also ossified, so that he was, as it were, completely pinioned. Besides all this, the subject in question had numerous other exostoses on various parts of his body. Mr. Abernethy gave, in this case, muriatic and acetic acids, with the view of dissolving the lime, which it was conceived might be too abundant in the system; but, even if this theory had been correct, and the acids capable of the chemical action intended, after passing into the circulation, how could they be expected to dissolve only the redundant depositions of phosphate of lime, and at the same time leave the skeleton itself undissolved?

When an exostosis depends upon lues venerea, it is almost always preceded by an acute pain, which in the beginning extends to nearly the whole of the affected bone, but afterwards becomes fixed to the point where the exostosis forms, and it is most severe in the night-time. When an exostosis is caused by scrofula, says Boyer, the pain is duller, or rather it is quite inconsiderable. It is the same with the exostosis which succeeds a blow, or contusion, without any manifest general cause. In the latter example, the pain, immediately excited by the accident, subsides in a few days, and the swelling occurs so slowly, that no notice is taken of it till it has attained some magnitude. (*Mal. Chir.* t. iii. p. 545.)

The disposition to the formation of ossific tumors may prevail throughout the system, and display itself in other textures besides the bones. Thus, Mr. Mayo refers to a specimen of ossification of the lungs, taken from a patient, who died of pulmonary disease after amputation of the leg for ivory exostosis. (See *Outlines of Human Pathology*, p. 14.) The alliance between the ossification of ligament, muscle, tendon, and exostoses, is well illustrated in Jeff's skeleton in the Hunterian Museum. In this remarkable instance, some of the ossifications form exostoses, while others pass from one part of the skeleton to another. The first prevail especially in places where muscles are inserted. The second have generally followed the course of the larger muscles, and may be seen on the right side, joining the clavicle and acromion to the humerus, in the situation of the supra spinatus, and passing from the lower angle of the scapula to the humerus in the course of the teres major and latissimus dorsi. On the back more extensive ossifications appear, which affix the scapulae to the sacrum and ilium, and to the spines of the lumbar and dorsal vertebrae. From the pelvis, ossifications extend in the direction of the glutæus maximus, biceps, and triceps. Ossifications of the tendinous and ligamentous parts are still more common, producing ankylosis of the vertebrae, left elbow, tibia and fibula, and of the bones of the tarsus to one another. (See *Museum Catalogue of the College of Surgeons*.)

Hydatids are occasionally found within exostoses, in which circumstance the former are sup-

posed to be the cause of the enlargement of the bone. A remarkable specimen of such a disease in the tibia is mentioned by Sir Astley Cooper. (*Surgical Essays*, part i. p. 163.) He refers also to a humerus, in the museum of St. Thomas's Hospital, where the shell of the bone is considerably expanded, the periosteum over it thickened, and in the seat of the cancellated structure are several hydatids, supposed to have been the cause of the enlargement of the exterior surface of the bone, as well as of the increase of its cavity. (*Vol. cit.* p. 161.)

A most interesting case of a bony tumor on the forehead, containing hydatids, was published by Mr. R. Keate. (*Med. Chir. Trans.* vol. x. p. 278.)

An exostosis constantly feels hard; but its size is various, and it may be indolent or painful. By these signs, and its firm adhesion to the bones, it may be always distinguished from other tumors. Some exostoses cannot be ascertained before death. Such was the case in which the parietal bone was found, after death, to be three times thicker than natural. Such also was the example, related in the memoirs of the Academy at Dijon, in which a person died from an exostosis on the internal side of the os pubis, the tumor having prevented the discharge of the urine, and the introduction of a catheter, by its pressure on the neck of the bladder.

Exostoses may be either *acute*, or *chronic*, in their progress. In the first case, which, according to Boyer, happens most commonly in the *cellular* or malignant exostosis, the appearance and formation of the tumor are quick; the swelling rapidly acquires a considerable size; and it is always preceded by, and accompanied with, continual violent pain, which the external and internal use of opium has little effect upon, and the intensity of which is not increased by pressure. The pain is sometimes so severe that it occasions a good deal of symptomatic fever. Boyer, who seems not to be aware of the origin of what he terms the *cellular*, and what Sir Astley Cooper has named *fungous exostosis*, from the medullary membrane, finds difficulty in accounting for the rapid growth and great sensibility of the tumor, considering the natural density of the bones, and the little energy of their vital properties.

In the hardest kinds of exostosis the tumor is preceded by no pain, or, if any, it is very slight; the tumor grows slowly; and although it sometimes attains a considerable size, its increase is attended with no particular sensibility, and no disturbance of the animal economy. (*Boyer*, op. cit. t. iii. p. 546.)

Our ignorance of the pathology of exostoses, particularly their causes, accounts for the imperfection of our treatment of them. With the exception of the venereal exostosis or node, there is no species of this affection for which it can be said that we have any medicine of efficacy.

Boyer advances it as a principle that the resolution of exostoses hardly ever happens, and that the greater part of the examples recorded in proof of the occurrence were nothing more than periostoses (p. 547).

However, a young woman was in the Middlesex Hospital with an exostosis of the humerus. It was sawn off, but grew again. A rubefacient plaster was applied, an abscess followed, and the new bone was absorbed. (See *Mayo's Human Pathology*, p. 13.) When abscesses form, exostoses are very

subject to be attacked with caries, or necrosis.

When an exostosis is hard, chronic, and free from pain and alteration of the structure of the bone, it is more common for it to cease to enlarge and remain stationary during life, without producing inconvenience, provided it be so situated as not to impede the functions of any vital organ.

But, in the *cellular* exostosis of Boyer, which I take to be the same disease as the *fungous* exostosis of the medullary membrane of Sir Astley Cooper, and which is of a malignant character, the acute and rapid progress of the disease indicates a deeper and more serious alteration of the texture of the bone. A part of the tumor usually consists of a pultaceous, or gelatinous matter, and the rest, still endued with its natural organisation, though altered by the disease, soon presents one or several cavities, in which there is suppuration. At the same time, the external soft parts, being excessively and rapidly distended, inflame, ulcerate, and leave exposed a more or less extensive portion of the tumor, the disease of which has in many cases been very wrongly supposed to be caries. It is not, observes Boyer, that the part of the swelling denuded by ulceration is not sometimes affected with caries; but then it exists as a complication of the original disease, and as a particularity, by no means the result of the ulceration of the soft parts, and of the exposure of the diseased bone to the contact of the air. When the soft parts are thus ulcerated, the opening contracts to a certain point, and becomes fistulous. The suppuration is always of bad quality, and in a quantity proportioned to the size of the cavity of the abscess and the strength of the patient. The fever, which commences at an early period of the disorder, assumes a slow type, and its continuance, together with the copiousness of the ichorous discharge, the irritation, &c. may bring on the patient's dissolution.

The following are the symptoms of what Sir Astley Cooper denominates the *fungous exostosis of the medullary membrane*. The disease begins with a general enlargement of the affected part of the limb, extending a considerable way around the seat of the exostosis itself. This form of the complaint mostly occurs in young persons, though Sir Astley Cooper has seen it in an individual fifty years old. "Its increase proceeds very gradually; and even when it has acquired considerable magnitude, although it produces some diminution of motion in the limb, it does not occasion pain, nor prevent the patient from using it. When any pain does arise, it is of an obtuse kind, only being acute in the event of a nerve being stretched by the tumor. Thus an exostosis of the thigh-bone sometimes causes great agony, by pressing on the sciatic nerve. Paleness, debility, and irregularity of the bowels are observed to attend the early stage of the disease; and afterwards the complexion becomes sallow. In the mean time, the diseased part of the limb attains an enormous size; but the skin retains its natural colour. At many points the swelling feels hard; at others, it is so elastic as to cause the presence of fluid to be suspected; but, if an opening be made, only blood is discharged. The surface of the tumor next becomes tuberculated, and the prominences tender, and their surface is often slightly inflamed. The rest is now broken, the appetite impaired,

and the bowels become extremely irregular. At length the tubercles ulcerate; the skin secretes pus; but, when the swelling itself is exposed, it discharges a bloody-coloured serum. A fungus then forms, which sometimes bleeds profusely, and, after it has risen very high, sloughing occurs, and considerable portions of the swelling are thrown off. But, although the swelling may be lessened by this process, Sir A. Cooper has never known the disease cured by it; and, in the end, the patient is destroyed by the effects of the repeated bleeding, immense discharge, and constitutional irritation." In this disease, as in common fungus hæmatodes, tumors of a similar nature are often formed in other parts of the body, and, after the amputation of the affected bone, frequently make their appearance in organs of the greatest importance to life. The swelling is described as originating from the medullary membrane, and as removing the muscles to the distance of three inches, or more, from the bone, so that they represent a thin layer spread over the tumor. The blood-vessels and large nerves are also similarly displaced. The tuberculated appearance of the skin, which is itself sound, is caused by projecting small masses on the surface of the tumor. Under the muscles is the periosteum, pushed to a considerable distance from the bone. A part of the swelling itself is yellow, like fat; another portion resembles brain; and a third is composed of coagulated blood with interstices filled with serum. In some parts, the white substance is found nearly as firm as cartilage; but in general it presents a more spongy appearance, and is interspersed with spicula of bone. The shell of the bone itself is in part absorbed; in some places it is only thinner than usual; while in others it is immensely expanded, so as to form a case like wire-work over the tumor. The fungous granulations, proceeding from the medullary membrane itself, are exceedingly vascular, and often shoot from the cavity of the bone beyond the level of the integuments. *Sir A. Cooper, Surgical Essays, part i. p. 165—168.*)

One termination of exostosis, not sufficiently noticed by writers, but which has been observed, especially in the hard and stalactical exostosis, is that by necrosis. Tumors of this description, after acquiring a large size, have been attacked by necrosis, separated from the bone which served them as a base, and been surrounded with a reproduction in every respect similar to that with which nature surrounds sequestra formed under any other circumstances. This termination is undoubtedly the most favourable of all, because nature proceeds in it slowly, without any violent disturbance; but, unfortunately, it is the least common. Art can imitate it; but her means are very inferior to those of nature. (*Boyer, Mal. Chir. t. iii. p. 547—550.*) A few years ago a most interesting case of an enormous exostosis of the upper maxillary bone, which followed the preceding course, was under my notice. It was believed at first to be a malignant tumor of the antrum; but the bony formation, after exciting abscesses, was attacked with necrosis, and was ultimately thrown off by exfoliation.

The hardest exostosis, which has grown slowly and without causing severe pain, is the least dangerous of all. After the disease has attained a certain size, it may become stationary, and continue in this state, without inconvenience, during life. This is most frequently observed in the *ivory* ex-

ostosis; and I join Boyer, and others, in not considering this case as at all disposed to malignancy. Without having precisely this extreme hardness, however, some exostoses, which are tolerably solid, and in which the natural organisation of bone is still distinguishable, are capable of undergoing a slight reduction, after the removal of their cause by nature or art. Boyer states that this sometimes happens in a few scrofulous exostoses, and particularly in such as are venereal, and not of large size.

The *cellular* exostosis of Boyer, the *fungous* exostosis of Sir A. Cooper, and the cases which are named *osteosarcomata*, are the most serious of all, especially when the texture of the bone is considerably altered, and the disease is in a state of ulceration. The rapid formation of the disease, the violent shock which it imparts to the constitution, and the hectic disturbance which it excites, generally bring the patient into imminent danger, and commonly leave no other resource but that of amputating the limb.

The treatment of exostoses is to be considered in a medical and surgical point of view. When any general cause of the disease is known, or suspected, such cause is to be removed by those means which experience has proved to be most efficacious. Thus Boyer recommends mercurial and antiscrofulous remedies, &c. according to the nature of the case. At the present day, iodine, and the iodide of potassium are frequently prescribed.

Whatever may be the species of exostosis, or the nature of its cause, relief, says Boyer, may be derived from the outward use of opium, whenever the disease is attended with severe pain. He speaks favourably of the application of a linseed-meal poultice, mixed with a decoction of the leaves of nightshade and henbane, to which a strong solution of opium has been added. But he thinks that an antiphlogistic plan, with bleeding, is hardly ever admissible, because it weakens the patient too much in so tedious a disease, and can only be a palliative, incapable of curing, or preventing, the ravages of the disorder.

When there is no pain, or it has been appeased, during or after any general method of treatment, the surgeon may try resolvent applications, particularly soap, and mercurial plasters, the tincture or ointment of iodine, the liniment of ammonia, bathing in water containing a small quantity of soda, or potassa, hydro-sulphuretted washes, &c. It must be confessed, however, that the progress of exostoses can scarcely ever be checked by any general methodical treatment. The muriatic and acetic acids have been administered, but without effect; nor am I acquainted with any remedies which possess efficacy, except iodine and mercury, which last we know will rarely answer, except in cases of nodes. In the commencement of any deep-seated disease in a bone, Sir A. Cooper thinks that the best medicine for internal exhibition is bichloride of mercury in small doses, together with the compound decoction of sarsaparilla. (*Surgical Essays*, part i. p. 169.) Boyer is firmly of opinion that, with the exception of recent small exostoses, the nature of which is even doubtful, the resolution of such tumours is almost impossible. A slight diminution of the swelling, and its becoming perfectly indolent, are the most favourable changes which can be hoped for, whether they occur spontaneously, or are the

fruit of surgical assistance. (*Mal. Chir.* t. iii. p. 554—557.)

Blisters have often been applied to the skin over exostoses, and kept open for a long period with savine ointment; but, although they tend to diminish venereal nodes, after they have been lessened as much as they can be by specific treatment, their efficacy in cases of exostoses has not been considerable. However, a trial of them in some examples is rational; and Sir Astley Cooper approves both of leeches and blisters, a discharge from the latter being kept up with equal parts of the mercurial and savine ointments. (*Surgical Essays*, part i. p. 169.)

When non-malignant exostoses merely occasion a deformity, and no pain, nor inconvenience, from the pressure which they produce on the neighbouring parts, it is certainly most advisable not to undertake any operation for their removal; for, as Boyer has truly observed, in by far the greater number of instances the local affection is much less to be dreaded than the means used for removing it.

Caustics and the cautery have occasionally been applied to exostoses; but they mostly do mischief. Boyer mentions a woman, in whom some caustic was applied to an exostosis at the inside of the tibia; but which, instead of removing the tumor, caused a necrosis, of which she was not well two years afterwards. In a few instances, however, after the removal of cartilaginous exostoses, of the interior of a bone with cutting instruments, the application of the cautery has prevented a reproduction of the diseased mass, as we find exemplified in a case recorded by Sir Astley Cooper, where such a disease of the jaw was thus extirpated. (*Surgical Essays*, part i. p. 158.) The bold and successful manner, also, in which the hydatid exostosis of the head was attacked with the saw, caustics, and the actual cautery, by Mr. R. Keate, is particularly entitled to the attention of the surgical practitioner. (*Med. Chir. Trans.* vol. x. p. 288, &c.) I have already noticed the occasional cure of true exostoses, not malignant ones, by an accidental attack of necrosis. Mr. Travers, aware of this important fact, has suggested the practice of removing the periosteum in some cases, for the purpose of producing the death and exfoliation of the swelling, or a part of it, when circumstances render some attempt to get rid of it urgently necessary.

So far as my information extends, no attempts to stop the progress, and effect the cure of a fungous or malignant exostosis, by tying the main artery of the limb, has ever yet succeeded. Two cases, proving the inefficiency of this practice, are detailed by Sir A. Cooper. (Vol. cit. p. 170.)

As the *fungous exostosis of the medullary membrane* is evidently connected with a state of the constitution analogous to what prevails in fungus hæmatodes (see *this word*), the permanent success of amputation should never be too boldly promised; but as no medicines have any material power over the disease, and the operation is the only chance of relief, it ought to be advised.

Cartilaginous exostoses of the medullary membrane may sometimes be extirpated by removing their outer bony covering, and then cutting away the cartilaginous matter closely from the bony surface to which it is attached. Sometimes, as I have noticed, these measures are followed by the use of the actual cautery.

Periosteal exostoses are also either *cartilaginous*, or *fungous*, which latter are attended with less general swelling of the limb, and are more prominent than fungous exostoses of the medullary membrane. Ulceration, bleeding, sloughing, and great discharge ensue, and, unless some operation be performed, the patient loses his life. (Sir A. Cooper, *Surgical Essays*, part i. p. 180).

The *cartilaginous exostosis*, *between the periosteum and bone*, arises from inflammation of the periosteum, and subjacent part of the bone; and a deposition of firm cartilage, adherent to both these surfaces, takes place. In this substance bony matter is secreted, which is first thrown out from the original bone. As the cartilage increases in bulk, the quantity of phosphate of lime augments, and fresh cartilage is constantly deposited upon the outer surface of the tumor. On dissection;—1st, the periosteum is found thicker than natural; 2ndly, immediately below the periosteum, cartilage; and 3rdly, ossific matter, deposited within the latter from the shell of the bone, nearly to the inner surface of the periosteum. When the growth of such a swelling ceases, and the disease is of long standing, the exterior surface consists of a shell of osseous matter, similar to that of the original bone, and communicating with its cancelli, in consequence of the primitive shell having been absorbed. (Sir A. Cooper, *Surgical Essays*, part i. p. 186.) The *periosteal cartilaginous* exostoses constitute the indolent, hard forms of the disease. In their early stage, especially when dependent on syphilis, they may be checked by small doses of mercury, the decoction of sarsaparilla, and the emplastrum ammoniaci cum hydrargyro. (Vol. cit. p. 196.) When large, or troublesome, they may be sawn away, as Sir A. Cooper states, without danger, if the disease be well discriminated from the fungous swelling.

When non-malignant exostoses are productive of much pain, and injure the health, and their situation admits of their being safely removed, with the aid of suitable saws, bone-nippers, or even of a gouge and mallet, the operation may be undertaken. Many tumors of this kind, however, have bases so very extensive and deep, that, when situated on the limbs, amputation becomes preferable to any attempt made to saw or cut away the exostoses, and preserve the members on which they are situated.

When the part by which they are connected to the bone is slender, their removal is generally a business of facility. I have heard of cases in which they were accidentally broken off, and lay loose, before the operation was begun.

In removing an exostosis, its base must be as freely exposed by the knife as circumstances will allow, and to this part a small fine saw may be applied. In cutting away some exostoses, the flexible saw, described by Dr. Jeffray, of Glasgow, has been occasionally employed. Mr. Hey's saws, and the semicircular trephine, are now so well known to the profession, that I scarcely need recommend them to be remembered in the present cases. Mr. Machell, a surgeon in London, invented a saw, well calculated for cutting a bone at a great depth, without injuring the muscles. It is a small, fine, perpendicular wheel-like saw, turned by means of a handle connected with machinery. It is highly commended by Sir A. Cooper, who has given a drawing of it in his

Surgical Essays, part i. An orbicular saw, invented and used by Professor Graefe, of Berlin, likewise merits particular notice on account of its ingenuity. (See C. G. E. Schwalb, *De Serra Orbiculari*, 4to. Berol. 1819). I would likewise recommend to the notice of surgeons the ingenious rotation saw, contrived by Professor Thal of Copenhagen, and of which a description and engraving may be found in the *Edin. Med. and Surgical Journal*, No. lxxiv. A strong pair of bone-nippers, and especially cutting forceps, the edges of which are in the line with the handles, will also be useful.

[The reader will observe that, in this article, Mr. Cooper has included under the head of Exostosis most of the tumors occurring in the bony tissue, whether of an innocent or of a malignant character; whether composed entirely of bone, of cartilage, or of these materials combined with various morbid products. Further information on many of the diseased states touched upon in this article will therefore be found under the appropriate heads of TUMORS, OSTEOSARCOMA, CANCER, FUNGUS HÆMATODES, &c. Mr. Stanley, in his "Treatise on Diseases of the Bones," published in 1849, enumerates the following products as occurring in the tumors of bone:—1. Cartilaginous substance. 2. Osseous substance, including the ivory and chalk-like deposits. 3. Encephaloid, or brain-like substance. 4. Fibrous substance. 5. Gelatinous substance. 6. Fatty substance. 7. Soft and very vascular substance, of the character of erectile tissue. 8. Fluids of various kinds, sanguineous, serous, or gelatinous. Mr. Cooper has treated sufficiently of the majority of these morbid conditions, causing outgrowths or tumors of bone. The osteoid cancer of Müller (*Archiv*, 1843, p. 396), or, as Mr. Stanley calls it, "Malignant osseous tumor," has been made known to the profession since the last edition of this Dictionary: the following brief outline of this affection is therefore here added.

The osteoid or malignant osseous tumor usually selects for its site the lower extremity of the femur, just above the condyles, or the upper extremity of the tibia, immediately below the head of the bone. It occurs also, but less frequently, in the flat bones, such as the ilium, or bones of the skull. According to Mr. Paget (*Lectures on Surgical Pathology*, p. 496), out of twenty-five cases, as many as thirteen occurred in the lower part of the femur. The skull, tibia, humerus, ilium, and fibula were each affected in two cases, and the ulna and metacarpus each in one case.

It may spring from the interior or exterior of the bone, and be composed of an osseous blended with a fibrous tissue. The former may be of an ivory hardness, or of a chalk-like consistence, and the latter, which is of a greyish-white colour, is found to pervade the osseous material, and to cover its surface.

The tumor is generally of an oblong form, with smooth surface and outline, and when occurring in a cylindrical bone, usually surrounds the whole circumference of the bone. The malignancy of this affection is chiefly indicated by the osseous contamination of the absorbent glands in the neighbourhood of the disease, and by the co-existence of malignant growths, and occasionally of osseous deposits in some of the internal organs, as revealed by post-mortem examination. In one instance numerous osseous tubercles were found after death

deposited under the pleura pulmonalis; in another, encephaloid matter invaded some of the viscera. These cases are usually as rapidly fatal as soft cancers, but marked exceptions occasionally occur.

The following case, one of three related by Mr. Stanley, sufficiently exemplifies the characters and nature of the malady:—A woman, thirty years of age, was admitted into St. Bartholomew's Hospital, with a hard and immovable tumor, occupying the upper half of the leg, and in the popliteal space there were two smaller, hard, but movable tumors. The large tumor had been eighteen years in progress, and the small tumors were of recent formation. The malignant character of the disease was indicated by sallowness of countenance, and collapse of the features. The limb was amputated through the lower third of the thigh. The large tumor was found to consist almost wholly of bone, which in one part presented the yellow colour and density of ivory, and in another was cancellous. The ivory-like portion of the tumor was continuous, with the same kind of deposit within the medullary tube of the tibia. The walls of the tibia were yellow, and of ivory-like density. The exterior of the tumor was composed of soft substance, which in some parts was fibrous and in others encephaloid. The smaller tumors in the ham were composed of osseous substance, partly ivory-like, and partly cancellous; and it appeared probable that they were formed by ossification of the absorbent glands. Within the medullary tube and cancellous texture of the femur there were deposits of ivory-like bone, and of soft substance, in some parts fibrous, in others encephaloid.

The stump healed soundly. Cough and difficulty of breathing ensued, and continued to the death of the patient, two months after the removal of the limb.

Numerous isolated ivory-like deposits, mixed with fibrous and encephaloid substance, were found within the medullary tube of the remaining portion of the femur. The femoral, iliac, and cervical absorbent glands were converted into fibrous and encephaloid substance, with osseous deposits in its centre. Many encephaloid growths were found in the pleura, pericardium, and lungs; and there was a large mass of the same substance deposited around and within the coats of the vena cava superior.]

EXTRAVASATION (from *extra*, out of, and *vas*, a vessel). A term, applied by surgeons to the passage of fluids out of their proper vessels, or receptacles. Thus, when blood is effused on the surface, or in the ventricles of the brain, it is said that there is an *extravasation*. When blood is poured from the vessels into the cavity of the peritoneum, in wounds of the abdomen, or when the contents of any of the intestines are effused in the same way, surgeons call this accident an *extravasation*. The urine is also said to be *extravasated*, when, in consequence of a wound, or of sloughing, or ulceration, it makes its way into the cellular substance, or among the abdominal viscera. When the bile spreads among the convolutions of the bowels, in wounds of the gall-bladder, this is a species of extravasation. In wounds of the thorax, or abdomen, an extravasation of blood also frequently happens in the cavity of the pleura or peritoneum. Large quantities of blood are often extravasated in consequence of vessels being ruptured by violent blows: in the scrotum, on the shoulder, and under the scalp, this effect is observed with particular frequency. (See ECCHYMOsis.) In the articles, HEAD, INJURIES OF, and WOUNDS, I have treated of extravasations of blood in the cranium, chest, and abdomen.

EYE, CANCER AND EXTIRPATION OF, One of the well-known characters of carcinoma in general is to attack persons advanced in age, rather than children and young subjects.

According to Scarpa, and, indeed, the sentiments of several other surgeons of the present day, cancer is always preceded by scirrhus, or a morbid induration of the part affected. As the disorganisation increases in this hard scirrhus substance, an ichorous fluid is formed in cells within it, and afterwards extends towards the external surface of the tumor, causing ulceration of the investing parts. The compact and apparently fibrous mass is then converted into a malignant fungous ulcer, of a livid, or cineritious colour, with edges everted, and irregularly excavated, and with a discharge of acrid, offensive sanies. The scirrhus, composing the base of the malignant fungus, instead of increasing in size, now rather diminishes, but retains all its original hardness, and, after arising a certain way above the ulcerated surface, is destroyed at various points by the same ulcerative process from which it originated. And, if any part of the livid fungous sore seem disposed to heal, it is a deceitful appearance, as, in a little time, the smooth points are again attacked by ulceration. To relate in this place all the differences between cancer and fungus hæmatodes of the eye would be superfluous, as the subject is elsewhere considered (see CANCER and FUNGUS HÆMATODES); but I may briefly advert to a few remarkable points of diversity. 1st, The primary origin of fungus hæmatodes is generally in the choroid. 2ndly, True cancer of the eyeball, when it begins on any part of the organ itself, instead of commencing as fungus hæmatodes at the deepest part of the eye, may originate in any of the coats of the eye. 3rdly, Cancer of the eye appears to Scarpa less destructive than fungus hæmatodes, because it begins on the exterior parts of the eye, so that whatever relates to the origin and formation of the disease is open to observation; and because a cancerous fungus on its first appearance, is not, according to his views, actually malignant, but becomes so in process of time, or from improper treat-

ment, previously to which period good surgery may be employed with effect. In this light Scarpa regards many excrescences on the conjunctiva and anterior hemisphere of the eye, which appear in consequence of a staphyloma of the cornea long exposed to the air and ulceration; those which arise from relaxation and chronic inflammation of the conjunctiva; from ulceration of the cornea, neglected or improperly treated; from violent ophthalmia, not of a contagious nature, treated in the acute stage with astringent and irritating applications; from suppuration of the eye, rupture of the cornea, and wasting of the eyeball; or from blows or burns on the part. Nothing, says Scarpa, is more probable than that all these ulcerated fungi were, on their first appearance, not of malignant character, or certainly not *cancerous*, and that many of them were not actually so at the time of a successful operation being done.

Now, in the opinion of the same valuable author, there is no criterion as yet known of the precise time when a sarcoma of the eye changes from the state of a common ulcerated fungus to that of carcinoma; for the exquisite sensibility, darting pains, rapidity of growth, colour, and ichorous discharge, are not an adequate proof of cancer. The symptom, however, on which he is inclined to place the greatest dependence, as a mark of the change in question, is the almost cartilaginous hardness of the malignant ulcerated fungus, which induration, he asserts, is not met with in the benign fungus, and never fails to precede the formation of cancer. (See *Scarpa, On the Eye, transl. by Briggs*, edit. 2, p. 511—513.)

4thly. The last difference of fungus hæmatodes from cancer of the eye, here to be noticed, is the pulpy softness of the whole of the diseased mass, in the first of these diseases; a character completely opposite to the firm almost cartilaginous consistence of the carcinomatous fungus.

What is termed fungus hæmatodes may be composed of a combination of medullary, erectile, and melanotic matter; but in other instances, either of the latter may exist as a separate disease, different from fungus hæmatodes. (See ANEURISM by ANASTOMOSIS, NÆVI, and MELANOSIS.) For the diagnosis of cancer in the interior of the eye see OPHTHALMOSCOPE.

Before describing the operation of removing an eye, affected with malignant disease, the following corollaries, drawn by Scarpa, should be recollected.

1. The complete extirpation of the eye, for the cure of fungus hæmatodes, although performed on the first appearance of the disease under the form of a yellowish spot, deeply seated in the eye, is useless, and rather accelerates the death of the patient. But, although this statement, made by Scarpa, is mostly true, modern experience justifies the hope that exceptions to the foregoing melancholy inference are possible. Thus Mr. Wishart removed from a boy, nine years old, an eye that had been affected with fungus hæmatodes about four months, and no relapse had taken place eighteen months after the operation. (See *Edin. Med. and Surg. Journ.* No. lxxvi. p. 51.)

2. The exterior fungus excrescence of the eye, commonly called carcinoma, beginning on the conjunctiva and anterior hemisphere, *while it is soft, flexible, and pulpy*, although accompanied with symptoms similar to those of carcinoma, is not actually this disease, nor does it become ma-

lignant and strictly cancerous, until it is *rigid, hard, coriaceous, warty, and, in every respect, scirrhus*.

3. The inveterate fungous excrescence, hard to the touch in all its parts, covered with ulcerated warts, which has involved the whole of the eyeball, optic nerve, and surrounding parts, and rendered the bones of the orbit carious, and contaminated the lymphatic glands behind the angle of the jaw, and in the neck, is incurable.

4. On the contrary, the partial or total extirpation of the eye will succeed, when attempted before the external fungous excrescence has changed from the state of softness to that of a scirrhus, warty, and carcinomatous hardness. (Vol. cit. p. 526.)

The operation of removing the eye is commonly believed to have been first performed in the sixteenth century by Bartisch; but, as M. Velpeau observes, it had probably been executed at a much earlier period, for J. Lange, who published in 1555, states that he succeeded in reducing into the orbit an eye, which some other surgeons wished to extirpate. (*Nouv. Elém. de Méd. Opér.* t. i. p. 781.) Bartisch employed an instrument, shaped like a spoon, with cutting edges, and by means of which the eye was separated from the surrounding parts, and taken out of the orbit. Fabricius Hildanus preferred a sort of probe-pointed bistoury. Bidloo made use of scissors and a pointed bistoury.

Until the time of M. Louis, no precise directions had been given about the mode of performing the operation: his method consists in dividing the attachments of the eye to the eyelids; then those of the inferior oblique muscle; next, those of the superior oblique muscle; then those of the levator palpebræ superioris, varying, according to their insertions, the manner of holding the knife. The eyeball is afterwards detached, and the four recti muscles, and optic nerve, divided with a pair of scissors.

The following is the ordinary method:—

1st Stage. Two semilunar incisions are first to be made at the base of the orbit, and the eyelids are to be detached from it, and dissected away with the rest of the tumor. But, when the eyelids are to be preserved, the first step consists in making an incision about an inch in length, through their external commissure. The eyelids are then to be everted, and the front of the tumor is then to be taken hold of with a tenaculum, single or double, or a ligature may be passed across it.

2nd Stage. The point of the knife is then introduced at the inner angle, and passed close to the ethmoid bone nearly down to the foramen opticum. It is then to be conveyed across the floor of the orbit, so as to divide the attachment of the inferior oblique muscle, the connection of the conjunctiva to the eyelid, and some adipose and cellular tissue. It is next to be brought again to the inner angle, and, with the edge turned upward, the superior oblique muscle is to be cut, and the blade carried across the upper part of the orbit, in which movement some operators endeavour to cut out also the lachrymal gland, as the knife is about to unite the two incisions near the external angular process.

3rd Stage. The eye is now only retained in the orbit by a kind of pedicle, composed of the four recti muscles and the optic nerve. Sup-

posing the operator prefers dividing it with scissors, they may be introduced on the nasal side of the orbit, with their concavity towards the swelling, and while the swelling is drawn forwards and outwards the pedicle may be divided at one stroke. If any fibres should remain uncut, their division must now be completed. If a long, narrow knife is preferred, it may also be introduced on the nasal side of the orbit, as recommended by Velpeau. (*Nouv. Elém. &c.* t. i. p. 787.) This gentleman, however, does not object to introducing the knife or scissors on the temporal side as preferred by Desault, Travers, Lawrence, and Malgaigne. The lachrymal gland is best removed by seizing it with a hook, and then dissecting it out of its fossa. Dupuytren used to begin with detaching the eye from the upper part of the orbit; he then divided the pedicle, and drew the swelling towards the cheek. The operation was finished by detaching the tumor inferiorly, from within outwards. Thus, there were only two stages. (See *J. F. Malgaigne, Manuel de Méd. Opér.* ed. ii. p. 402, 12mo. Paris, 1837.)

Mr. Travers, with a straight double-edged knife, freely divides the conjunctiva and oblique muscles, so as to separate the eyeball and lachrymal gland from the base of the orbit. Drawing the eye then gently forwards with the ligature, he introduces a double-edged knife, "curved breadth-wise," at the temporal commissure of the lids, for the purpose of dividing the muscles, vessels, and nerves, by which the globe remains attached. The hæmorrhage he represses with a small bit of fine sponge put into the orbit, and a light compress, applied over the eyelids, and supported with a bandage. The sponge, he says, should not be suffered to remain longer than the following day, when a soft poultice in a muslin bag may be substituted for the compress. He approves of giving an opiate at bed-time, and joins Ware in condemning the practice of cramming the orbit with lint or charpie, and leaving it to be discharged by suppuration. (*Synopsis of the Diseases of the Eye*, p. 308.)

As soon as the eyeball has been removed, the surgeon should examine with his finger whether any indurated or diseased parts have been left behind, and, if they have, he should next cut them away with scissors or the knife.

The employment of sponge is objected to by Velpeau as likely to cause some mischief by its expansion within a solid cavity. (See *Nouv. Elém.* t. i. p. 788.) If a dossil of lint be held for a little while on the bleeding vessels, the hæmorrhage will generally stop, and the plan of forcibly distending the orbit with lint, or sponge, will be unnecessary. The bleeding is from the ophthalmic artery and its branches. The bleeding having been stopped, the edges of the incision at the outer commissure are to be brought together with a suture; the eyelids approximated to one another; and some soft pieces of lint, or fine linen, wetted with cold water, laid over them.

For a few days after the operation antiphlogistic treatment is proper. The patient should be kept in bed until all risk from inflammation is past, and suppuration has been freely established. In one case, operated upon by Mr. Guthrie, the symptoms of inflammation were so violent that it was necessary to take away 250 ounces of blood in the course

of the three first days. (*Operative Surgery of the Eye*, p. 183.) Sometimes, fungous granulations continually form in the orbit, notwithstanding they are repeatedly destroyed; and sometimes the disease extends even to the brain, and produces fatal consequences. When malignant fungous excrescences grow from the cornea alone, it is necessary to extirpate the whole eyeball.

[The operation of excision, as above described, has been superseded by a method which was first performed by Mr. Critchett, at the Royal London Ophthalmic Hospital, Moorfields. The following remarks respecting the operation and its indications are taken from a paper of Mr. Critchett. (*Original Observations, founded on a series of cases of Extirpation of the Globe, &c.* reprinted from the *Lancet* of Nov. 17th and 24th, 1855.) "... and secondly to describe my method of extirpating the globe, an operation I first performed at the Ophthalmic Hospital, in October 1851, and one that I was the first to perform and to describe in this country. I have since learnt that it was first suggested by O'Ferrall, in 1841, in the *Dublin Journal*, and by Bonnet, in 1842, in the *Annales d'Oculistique*, but of this I was unaware at the time of my operation, as was Bonnet probably of O'Ferrall's priority when he wrote upon the subject a year subsequently. The patient is brought under the influence of chloroform. I then commence by dividing the conjunctiva as close as possible round the margin of the cornea. I then cut through the external rectus muscle, close to the sclerotic, then the superior and inferior rectus and the obliqui; then draw the globe forwards, and divide the optic nerve; turn the globe out of the orbit, and complete the operation by dividing the internal rectus. If rapidity of execution, absence of hæmorrhage, freedom from constitutional or local disturbance, and a speedy cure, form the elements of a mild operation, then I do not hesitate to rank this procedure, formerly deemed so severe, amongst the simplest and safest operations of surgery."

Mr. Dixon has modified this operation, by first dividing the internal rectus, so as to leave a considerable portion of its tendon by which to hold the eye, then dividing, without using the hook, the tendons of the superior and inferior muscles and the optic nerve; the globe is then turned out of the orbit, and the external rectus tendon, and the remainder of its soft attachments are divided. Mr. Bowman contracts the opening in the conjunctiva by a suture, when the bleeding has entirely ceased. The bleeding (generally inconsiderable, as only small vessels are divided) is best stopped by continued application of cold water, whilst the lids are kept open by the speculum. The introduction of lint does not answer as well.

Mr. Critchett proceeds to consider the cases for which he has performed this operation, and for which it seems applicable. He says, "I may mention that I have lately performed this operation in cases that I would group as follows:—1st. Extensive staphyloma of the globe, with and without recent inflammatory disease. This class of cases, however, is now treated by abscission. See STAPHYLOMA. 2nd. Cases where there is reason to suspect the presence of a foreign body within the globe. 3rd. Cases of severe symblepharon or adhesion of the globe to the eyelid, causing pain, irritation, and deformity, and for which no operation is of any avail. 4th. Acute inflammation

and pain in the globe, with loss of vision, occasioning great distress, and preventing the use of the other eye, or showing a constant tendency to severe relapses. 5th. Cancer; deep-seated disease of the globe, the result either of accident or of deep-seated inflammation, with disorganisation of all the structures, in which the other eye exhibits symptoms of sympathetic affections, threatening gradual failure of sight.

I am anxious, says Mr. Critchett, to explain and to illustrate each of these groups, and to show my reasons for performing this operation. 1st. In some of the more severe cases of staphyloma, where the entire globe is enlarged, the sclerotic thin, and the deep-seated vessels, both in the choroid and retina, much dilated, it is found that the ordinary operation of opening the globe is liable to certain rather serious inconveniences. When the humors have escaped, the vessels, deprived of the support to which they have been accustomed, give way, and rather profuse and protracted hæmorrhage often takes place, which first painfully distends the globe and then escapes through the lids. This is usually followed by severe inflammation and suppuration of the globe, which continues many weeks, is attended with very severe pain, and often leaves a considerable enlargement, which is prone, from time to time, to take on inflammatory action. In such cases, I am of opinion, that the removal of the globe is a far milder operation than opening it in the usual way for the operation of staphyloma. 2nd. I have now to consider those cases in which the presence of a foreign body is suspected in the globe, and is out of sight and out of reach, but produces pain, and sympathetically affects the other eye. In such cases I believe the removal of the globe is the best proceeding. I have also performed this operation in two cases of extensive adhesion between the globe and the lids. The one case was a girl, aged fourteen, whose eye had been extensively burnt with lime. The lower lid was completely adherent to the globe, and the upper lid was partially adherent; the entire rows of lashes of both eyes were turned in upon the globe, causing constant severe distress and preventing the use of the other eye. The operation perfectly relieved all the symptoms and deformity, and was, I believe, the only effectual means that offered. Extensive separation of the globe from the lids had been previously tried, and had quite failed. 3rd. I have now to consider, in the last place, those cases of deep-seated disease of the globe, the result either of accident or of idiopathic inflammation, with disorganisation of all the structures, in which the companion eye exhibits symptoms of sympathetic affection, threatening gradual failure of sight. The idea upon which this operation is founded, and which, I am free to admit, requires for its confirmation a large mass of evidence, takes its origin in the well-known sympathy that exists between the two eyes; in the symmetry of disease in these organs; in the frequent observation that when one eye has been destroyed, either by accident or disease, the other sooner or later becomes seriously compromised. The important problem to resolve is, how far the one is the result of the other. In those cases that result from accident, there can be little doubt of the close connexion between the two; in those resulting from disease, this is, perhaps, not quite so clear.

The removal of the globe has been until a recent period regarded as a very severe and repulsive operation; and such a remedy may be considered by some as somewhat heroic and hardly justifiable except in very extreme cases. If, however, we divest the inquiry of all preconceived prejudice, and carefully examine the naked facts of the case, how does it stand? Even suppose, for the sake of argument, that there is no truth in the idea that incipient disease in one eye may be so far dependent upon and connected with a disorganised condition in the other, that the removal of one suspends the disease in the other, still the operation may be useful. It is proposed to remove a part that is only termed by courtesy an eye, for it has forfeited every claim to that appellation: it is a mere bag distended with water, and containing, perhaps, some fibrinous and chalky debris, without any remains of that delicate nervous membrane to which the optical machine is subservient, and without a vestige of that function for which the eye was created. It is the seat of a slow inflammatory action, and forms a nidus for the sudden lightening up, at any moment, of acute disease, and is in itself a constant source of trouble. Surely it is no very cruel or unjustifiable act towards a patient to remove, by a safe and speedy operation, an organ that has lost its characteristic appearance, has ceased to perform its functions, and is a constant source of suffering, when its place may be artificially supplied so as to produce a much more satisfactory appearance than the diseased globe presented. If, however, we superadd to these considerations the possibility of removing incipient disease in the other eye, or even of arresting it at the point where we find it, the arguments in favour of the operation obtain an immense accession of strength, and a new element is introduced into the pathology and treatment of certain forms of eye-disease.

Since writing the above it has occurred to me that it may be objected to the views that I have endeavoured to set forth, that there is a large mass of cases constantly coming before our notice in which one eye has been lost, either from injury or disease, without the other sustaining any kind of damage. This circumstance does not, of course, invalidate the equally well-observed fact, that in many cases the second eye does suffer; but it seems, at first sight, to stand in curious antagonism to it, and requires some explanation. It has often engaged my careful attention, and after much observation I am inclined to think that it will be found that in those cases in which the second eye remains sound and healthy no disease is going on in the lost eye; it is in a perfectly quiescent state. On the other hand, wherever the second eye is becoming involved, the disorganised globe, whether from traumatic or idiopathic causes, is in a smouldering state, and breaking out, from time to time, into active disease.

It may also be objected to the views I have been endeavouring to set forth, that there seems no reason why the removal of a diseased globe should be followed, not only by arrest of disease in the other, but also by perfect recovery of its function. After all, the chief court of appeal must be to experience and to well-observed facts, which are at present necessarily scanty, from the short time that has elapsed since the operation was suggested. At the same time it appears to be in accordance with analogy, that the removal of a serious source of

irritation may not only produce an arrest in the progress of mischief in the other eye, but, by leaving the curative efforts of Nature in full force, undisturbed and undiverted by the presence of contiguous and incurable disease, may contribute towards perfect recovery.]

[EYE, EXAMINATION OF THE. It is often difficult to obtain a satisfactory view of the cornea, especially in children suffering from that irritable form of inflammation known as scrofulous ophthalmia. In such cases the surgeon should sit and spread a folded towel across his knees; opposite to him sits the attendant, who secures the child's hands, and lowers him backwards until his head is received between the surgeon's knees, and there held as in a vice. The extreme tip of the fore-finger, with a bit of rag twisted over it to prevent its slipping, having been laid upon the middle of the upper tarsus, at the very edge—between the roots of eyelashes and the globe—the lid, without any dragging of the skin, is to be steadily pushed in a direction which, in the erect position of the body, would be upwards and backwards. In this way the greater part of the cornea is at once exposed; but if the finger is allowed to drag the skin of the lid, the tarsal cartilage becomes instantly tilted over, and the conjunctiva, bulging forwards, hides the eyeball from view. The lower lid may be depressed by a similar manœuvre, but this is not necessary in examining the cornea, for that part is always rolled upwards under cover of the upper lid.

If a more prolonged examination of the eyeball be required, as in a case of ophthalmia neonatorum, a spring speculum must be employed, adapted, as regards width and strength of the spring, to the size of the palpebral fissure. (*Dixon, Diseases of the Eye*, 1858, p. 1.)

For examination of the parts behind the pupil, see article OPHTHALMOSCOPE.]

EYE, INJURIES OF THE. Wounds and other injuries of the eye, regarded as causes of

ophthalmia, Beer divides into three kinds; namely, *mechanical*, *chemical*, and *mixed*. A prick of the eye with a fine needle is an example of a simple mechanical injury; the action of quick-lime upon the organ is an instance of one purely chemical; and the violent propulsion of a red-hot bit of iron against the eye is a lesion, which may be said to be both mechanical and chemical. The same author makes a variety of original reflections upon the differences connected with the extent and intensity of such injuries. Their intensity, he views only as something relative; thus, either the force, with which the eye is injured, is of itself too great ever to be resisted, as is seen in a gunshot wound; or the organic powers of the patient are, from age, sex, or constitution, much too feeble for the eye to bear favourably any considerable injury, as is the case with children and weak unhealthy females; or the organisation of the eye itself may be weak, and the effects of the violence therefore greater, as exemplified in the fact of a brown or black eye generally bearing a wound better than a gray, or blue one; or, lastly, the organic powers of the texture of the eye, immediately injured, may be too feeble to bear even a slight lesion, as is the case with the retina. (B. i. p. 95.)

Mechanical injuries of the eye may be made either with sharp, or obtuse bodies. Sharp, pointed and cutting instruments are capable of readily penetrating the eye, without occasioning, at the moment of their entrance, any violent compression or laceration of the neighbouring textures, and consequently the injury inflicted is a simple puncture, or an incision. Sabre-cuts of the eye, however, are to be excepted; for, though the weapon may be sharp, the blow is always attended with more or less concussion, and injury of the textures adjoining the wound, which are very delicate and readily spoiled. Blunt weapons, or bodies, can only enter the texture of the eye by dint of great force, and in this case always cause a serious degree of compression, stretching, and laceration; but sometimes, when they do not penetrate the organ, the contusion is such as is productive of not less mischief.

In the case of a simple puncture, or incision of the eye, Beer seems to think that the subsequent ophthalmia is generally more owing to the incapacity of the wounded organ to bear the effects of the light, air, &c. than to the injury itself abstractedly considered. He observes, that a proof of the truth of this opinion is seen in the extraction of cataract; for if the operator is careless in the operation itself, opening the flap of the cornea very wide, so as to let the atmospheric air have free access to the inner textures of the eye; or if after the operation is finished he do not apply the dressings with caution, and properly darken the patient's chamber, he is letting the eye be subjected to some of the most active causes of inflammation. But though Beer is unquestionably correct in regard to the injurious effects of light on the wounded eye, it may be doubted whether his theories do not make him attribute too much to the irritation of the air and too little to that of the mechanical division of the parts.

In Beer's general observations on the treatment of inflammations of the eyes, the first indication specified is *to remove immediately everything, which is obviously producing an irritating effect upon the eye, and to take care that no fresh source*

of irritation to the organ incidentally takes place. And as it frequently happens, even in healthy, strong individuals, that ophthalmia is occasioned by foreign bodies, either lodged under the eyeballs, or inserted in some part of the eyeball, and not suspected to be there, the earliest attention should always be paid to their gentle and skilful removal. Easy as this object is of accomplishment, when not delayed, when the eye has not been seriously irritated by friction and pressure, and the patient is not of a weak, irritable constitution, it is often attended with great difficulty under one or the other of these circumstances, especially the last. In this case, strong convulsive rotations of the eyeball, followed by a violent and obstinate spasmodic closure of the eyelids, render it impossible to separate them; and the spasm is the stronger and more lasting, the more the extraneous substances are calculated, by their shape and chemical quality, to irritate the eye; and the greater the irritability of the patient is. In this state of things, every attempt forcibly to open the eye, or to examine it in the light, is not only useless, but increases and keeps up the spasm, which nothing will lessen and shorten except darkness and perfect repose. But, as timid, irritable persons are exceedingly apprehensive of the consequences of the lodgment of extraneous substances in the eye, the surgeon should endeavour to lessen their inquietude, by assuring them that every thing will be right again, which is strictly true when the foreign bodies are of the first class. Then the spasmodic closure of the eyelids will cease, and the extraneous substance admit of being properly taken away.

Success, however, does not always attend this simple method; for, in very weak subjects, the spasm of the orbicularis palpebrarum is so violent and obstinate, especially when a foreign body lodges in the eye, and at the same time mechanically and chemically irritates it (as is the case with particles of snuff), that it becomes indispensable to have recourse to medicinal applications. For this purpose Beer's experience has convinced him, that the best thing is a bread poultice, made either with milk or water, and containing some of the vinous tincture of opium. Care is to be taken, however, never to let it become quite cold during its application; for then the spasm would only be aggravated by it; and if such spasm has been of long continuance when the surgeon is first sent for, the poultice, according to Beer, may be rendered more efficacious by the addition of hyoscyamus to it. In irritable, hysterical, and hypochondriacal persons, such local treatment alone is frequently insufficient, and recourse must be had to the internal exhibition of antispasmodic anodyne medicines. At length, when the spasm of the orbicular muscle is so far diminished that the eyelids can be effectually opened without any force for the extraction of the foreign body, great caution and gentleness will yet be necessary, and, in particular, the eye should be kept in a very moderate light, as the spasm would be immediately excited again, either by sudden exposure of the eye to too much light, or rough handling of the eyelids.

Sometimes a person rubs his eye at first awaking in the morning, and if the eyelashes are very numerous and rigid, one of them will lodge between the eyeball and lower eyelid: it may rea-

dily be taken away with the end of a fine moist sponge, or camel-hair pencil, the eyelid being depressed as much as possible, and the eye itself turned upward, so that the hair may not be concealed in the fold of the conjunctiva. When the hair is situated under the upper eyelid (which Beer says rarely happens), it always lodges in the fold of the preceding membrane, whence it may be extracted in the manner above directed, with the difference that the eyelid must be raised or everted and the eye rotated downwards. (*Lehre von den Krankh. b. i. pp. 128—130.*)

Small globular smooth extraneous bodies, lodged under the eyelids, are very easily extracted, when the eyelid is gently taken hold of both by its edge and the eyelashes, and lifted up from the eye, while the patient inclines his head forwards, and the eye is turned completely downwards: the effusion of tears, excited by these manœuvres, will now generally wash these extraneous substances out of the eye, as they are not at all fixed. When the fissure between the eyelids is wide and open, but the eyeball at the same time very prominent, the object may also be easily accomplished, when the upper eyelid is gently and repeatedly stroked with the finger from the outer towards the inner canthus; in which case, the round smooth foreign body soon makes its appearance above the caruncula lachrymalis, whence it falls out of itself, or may be taken with the corner of a pocket-handkerchief.

The worst cases are those in which the eyes are very prominent, and the fissure of the eyelids small, as all the above methods are then useless, and only productive of irritation. In this circumstance, the eyelid is to be simply everted by taking hold of the ciliae, and drawing them forward and upward, while a probe is used for pressing back the upper portion of the tarsus. The foreign body may then be plainly seen, and easily removed.

Particles of common dust, and of sand and powders thrown over letters, which frequently get into the eyes of persons who open their letters carelessly, or, from short-sightedness, are obliged to bring them close to the nose, are generally more difficult of extraction. In the attempt, however, the eye must never be subjected to too much irritation. According to Beer, these extraneous particles of dust, or sand, may sometimes be removed by washing the eye well, or by dropping into it milk, or some other viscid fluid, while the patient lies upon his back, and the eyelid is lifted up from the eye. But, the most expeditious and certain plan is to employ a syringe, the pipe of which is to be introduced under the upper eyelid near the outer canthus, and the fluid thrown briskly in the direction towards the nose. If all the extraneous matter cannot be thus removed, the rest may sometimes be taken out, if the eyelid be everted in the manner above directed, which seems to me the right method to be adopted in several cases, for which Beer recommends other proceedings.

When particles of sugar, or other soluble, not very irritating substances, happen to insinuate themselves into the eye, professional aid is seldom requisite, as they generally dissolve in the tears, and are voided before a surgeon can arrive. Snuff, pepper, and other minute irritating bodies, as well as small winged insects, are to be removed in the same manner as particles of dust and letter-sand;

but particular care is to be taken afterwards to wash the eye well with some lukewarm mucilaginous collyrium, until the irritation, caused by the chemical effect of such foreign bodies, has been completely obviated.

The removal of foreign bodies of the second class is usually attended with more difficulty, because they, as well as those of the third class, more frequently produce a violent and obstinate spasmodic closure of the eyelids, and are seldom loose, being generally fixed in the cornea. However, when they happen to be detached, they may be extracted in the same way as small round smooth extraneous bodies, except that the stroking of the eyelid with the finger should be omitted, not only as useless, but likely to press any of these substances, which are of a pointed shape, into the loose conjunctiva, so as to injure the eye itself, which would otherwise not be hurt. The nibs of pens, the parings of the nails, and small hard-winged insects, when lodged in a depression of the cornea, or white of the eye, Beer says, may be easily dislodged by means of a small silver spatula, or a probe. Other foreign bodies of the second class are not only fixed in a depression, but even penetrate more deeply than the conjunctiva; and, in old subjects in particular, they often insinuate themselves into the loose cellular tissue under the conjunctiva, partly in consequence of the convulsive motions of the eyeball and eyelids, and partly by reason of the attempts made to loosen them. Hence, they frequently become situated a great way from the place of their entrance, and are completely covered by the conjunctiva. But, even when they lie immediately in the wound, they are so intimately connected with the subjacent loose cellular tissue, that every attempt to remove them with forceps is not only unavailing, but hurtful to the eye, inasmuch as the injury is thereby rendered deeper. They may be taken away with facility, however, when lifted up with a pair of small forceps, and cut away with a pair of scissors, together with the piece of cellular membrane, with which they are directly connected. If such extraneous substance should be actually underneath the sclerotic conjunctiva, Beer recommends the eyelids to be well opened, and the eye to be brought into a position, in which the part of the conjunctiva, covering the foreign body, is rendered tense, when an incision is to be made with a lancet down to the extraneous substance, which is to be taken hold of, and removed with a pair of scissors, the assistant being careful to keep hold of the eyelids during the operation. On the other hand, when the foreign body is actually lodged between the layers of the cornea, Beer considers that its extraction may be best accomplished with a lancet-pointed couching-needle. But, whatever instrument be used, its point must be passed with great caution closely and obliquely under the foreign body; and care must be taken not to introduce it too deeply, lest the anterior chamber be opened, which may readily happen in young subjects; and when it does, the aqueous humour flows out, and the cornea becomes so flaccid, that the removal of the extraneous substance is quite impracticable, before the puncture has healed, and the anterior chamber is again distended.

The removal of foreign bodies of the third class mostly demands very great caution, first, because,

as Beer observes, no particles of them should be allowed to remain in the eye, which without the utmost vigilance is apt to be the case; and secondly, because the wound of the eye, already considerable, should not be made larger than can be avoided. The extraction of small bits of glass is particularly difficult, as they cannot be seen, but must be found out entirely by the feelings of the patient, or the *tactus eruditus* of the surgeon, assisted with a probe. When, in this way, a particle of glass is detected, Beer directs us to take hold of it with a pair of forceps, and cut it away with scissors. The place, from which it has been removed, must then be carefully probed, in order that no other fragment may be left in it.

According to the same author, pieces of iron and steel, which strike the eye so forcibly as to enter it, as well as all other fragments of metals, which are readily oxidated, should be as carefully removed as bits of glass; for the more easily they combine with oxygen, and the longer they remain, the more brittle they become, and the more apt are minute particles to be left in the eye, especially in the cornea. A speck on the part of this membrane where the splinter has lodged, is the least serious consequence of such an event. When fragments of steel, which have quite a black appearance, remain fixed in the cornea several hours, it is found, after their removal, that the whole circumference of the depression, from which they have been extracted, is of a reddish-brown colour, produced by the rust left behind, and firmly adhering to the cornea. Every particle of rust must be carefully removed with a couching-needle, or else a permanent speck will ensue; but caution must be used not to puncture the anterior chamber. The extraction of particles of lead and gunpowder is generally difficult, as they have mostly been projected with great force against the eyelids, so as to produce not only a great deal of spasm, but instantaneous swelling of those parts. Hence, Beer says that they should commonly be taken hold of with forceps, and cut away. Particles of cantharides are easily removed with a small silver spatula, or the end of an eye-probe; but their violent chemical effect must be obviated by frequently applying to the part a little fresh butter, touching it with a camel-hair pencil, dipped in diluted liquor ammoniæ, or dropping into the eye lukewarm mucilaginous collyria.

The attempt to wash particles of quicklime, mortar, &c. from the eye, Beer says, only has the effect of rendering their violent chemical operation more diffused, and he recommends them to be taken out by means of a fine hair-pencil, dipped in fresh butter, or oil. This is the only way of immediately counteracting their chemical effect, and, after their extraction, the application of unctuous substances to the part should still be continued.

The stings of small insects, when lodged in the sclerotic conjunctiva, are often very difficult of detection; but they are more readily seen on the skin of the eyelids. Beer directs us to remove them with a pair of forceps, or a couching-needle, and then to have recourse to means calculated to diminish inflammation, which, in these cases, always begins on the first occurrence of the accident. Small shots, lodged in the loose cellular texture of the conjunctiva, must be cut out. In general,

says Beer, it is necessary to divide the conjunctiva, as they are mostly situated some distance from the place of their entrance, and of course are quite covered by that membrane.

As soon as a foreign body has been extracted from the eye, all precursors of ophthalmia diminish, as, for instance, the redness, intolerance of light, and the increased secretion and effusion of tears. Even the inflammation itself, when already developed, subsides; but this affection is slight, if the eye has not itself been injured by the extraneous body. On the other hand, when the eye has suffered more or less irritation from the nature of the substance itself, and the treatment requisite for its complete extraction, the inflammation may become more severe, unless the surgeon pay immediate attention to the degree of injury remaining. (*Beer.*)

According to the principles laid down in the foregoing columns, the first indication in the treatment of wounds of the eye in general is *to remove every kind of extraneous substance, which may impede the cure.* Hence, the necessity of observing whether the instrument with which the wound has been inflicted, or any part of it, is lodged in the eye. When this is the case, the foreign body should be quickly extracted, or else no recovery can take place. Beer relates a case, to which he was called, where a piece of tobacco-pipe had been driven so forcibly and deeply at the external canthus between the eyeball and orbit of a young student, aged 19, and of delicate make, that the eye was immediately pushed out of its socket, and on Beer's arrival, it lay with the cornea quite against the nose. Its very position led Beer to suspect that some extraneous body was lodged in the orbit, and notwithstanding the assurances of all the bystanders to the contrary, and the patient's being affected with violent spasms, the part was examined with a fine flexible whalebone probe, by which means, a piece of the pipe, nearly an inch in length, was felt and immediately extracted with a pair of forceps. Scarcely had this substance been removed, when the eyeball was spontaneously drawn back into the orbit, though with the cornea still turned towards the nose, and the twitchings of the muscles also instantly ceased; but the eye was blind, and had but a very faint perception of light. By careful treatment, the eyesight was restored in five weeks; but the eye could not turn towards the temple, owing to the considerable injury which the external straight muscle had sustained. With the aid of electricity, the power of rotating the eye about half its natural extent outwards was in the end regained, and the remaining infirmity resisted every method deemed worthy of trial. (*Beer, b. i. p. 146.*) See EXOPHTHALMIA.

Fragments of broken instruments are not the only kind of extraneous substances which may lodge in the wounded eye; for, as Beer observes, when the injury is extensive, contused and lacerated, there may be splinters of bone, or pieces of membrane, cellular substance, muscle, &c. so detached as to be quite incapable of reunion, on which account this author sets them down as foreign bodies requiring to be taken away. However, I conceive that with respect to the soft parts, the advice here delivered should be received with much limitation.

Wounds of the eye, like those of most other

parts of the body, may be healed either by direct union, or a slower process, in which suppuration, the filling up of the chasm by granulations, and the gradual, but not complete, approximation of its edges to each other, are the most conspicuous effects. Clean incised wounds may be cured in the first way (see CATARACT); and lacerated, contused wounds, or such as are attended with loss of substance, in the second. But, whichever plan be attempted, the eye must be kept quiet, and excluded from the air and light.

In healthy individuals, small punctures of the eye, made with instruments like needles, and perforating only the conjunctiva, or cornea, but not reaching the deeper textures of the organ, are generally followed by no serious consequences, even when all the aqueous humor is voided. It is only necessary to keep the eye quiet, and the air and light excluded from it by means of a light compress, suspended over it from the forehead. Under this treatment, such punctures are so firmly closed in twenty-four hours, without any opacity, that the chambers are nearly filled again with aqueous humor, and the intolerance of light, which was only the effect of the loss of that fluid, is entirely removed.

In large clean cut wounds of the eye, whether accidental or made in the extraction of cataract, the prognosis must be very cautious, and the treatment conducted with the utmost care; for, says Beer, it too readily happens, that, though the wound is not important in itself, its effects become from the least mismanagement, highly dangerous to the eye. Hence, when the patient is known to be either an individual not likely to take proper care of himself, or one too much alarmed about the fate of his eye, the prognosis should be very guarded, even where the constitution is of the best description, because a violent and dangerous attack of ophthalmia is apt to ensue and destroy the eye, sooner than effectual succour can be administered. On the other hand, when the patient is steady and intelligent, and the case is properly treated, the prognosis is favourable.

In considerable cuts of the eye, it is only possible to promote their union with a suitable bandage, and by effectually preventing all motion of the eye and eyelids, which is best accomplished, when the sound, as well as the injured eye, is covered, and the patient kept quiet in bed until the sides of the wound have grown together. (*Beer, b. i. p. 164.*)

As cases of deeply penetrating wounds of the eyeball itself, Beer enumerates the punctures made in the depression and reclinacion of cataract, and in every mode of forming artificial pupils; lacerations of the conjunctiva with ears of corn, pointed pieces of iron, splinters of wood, &c. In these cases the prognosis, he says, is always favourable, when the patient can put himself under all the conditions which the treatment requires, and his constitution is good. The first thing here to be carefully fulfilled, is the removal of any fragments of the instrument or body with which the injury has been inflicted, and it should be recollected that, in these cases, minute splinters, which are scarcely discernible, frequently lodge in the conjunctiva, and, if not immediately traced and removed, produce the worst consequences.

With respect to lacerated wounds of the cornea, they either penetrate the anterior chamber, or not.

They are all of them attended with more or less concussion, laceration, stretching, and partial contusion, of the delicate anterior textures of the eyeball; a consideration, as Beer observes, materially affecting the prognosis. When in such injuries of the cornea, inflammation and suppuration cannot be prevented, or the discharge is protracted, an obvious scar is always the consequence, which, when situated in the centre of the cornea, is a serious impediment to vision. Every endeavour should therefore be made to unite the wound by the first intention; and the best chance will be afforded by treating the eye precisely in the same manner as after the extraction of a cataract. (See CATARACT.) And when the plan fortunately succeeds, the flow of the aqueous humour out of the eye ceases in about 36 or 48 hours, and the anterior chamber becomes distended again; but the site of the injury continues visible for some time afterwards. The speck, however, ultimately disappears, though much sooner in young, healthy subjects than in the aged and feeble. When the opacity does not go off of itself, Beer finds a collyrium, containing some of the lapis divinus (see LACHRYMAL ORGANS) and the vinous tincture of opium the most effectual means of dispersing it. Through large wounds penetrating the cornea near its edge a fold of the iris is apt to protrude, and when it does it should be replaced, which can only be effected without mischief to the eye by gently rubbing the upper eyelid, and then letting a strong light suddenly strike the organ. In this case, the employment of instruments is considered by Beer highly objectionable. When the iris is not immediately reduced, it, as well as the cornea, is attacked with inflammation, and soon becomes firmly adherent to the edges of the wound. (See IRIS, *Prolapsus of the.*)

Large wounds penetrating the eyeball, and reaching the iris, are always of a very serious nature, even though the latter part may have received only a prick, or cut, because, as the injury has been produced by accident, and not by art, the wound of the iris cannot be free from all laceration and contusion. It is incredible, says Beer, what extensive injuries the iris will bear in healthy individuals at its pupillary and ciliary edges, especially when produced by very sharp instruments; nay, rents may happen at both its edges, without any ill consequences, if the constitution be favourable; a proof of which fact is seen in the two common methods of forming an artificial pupil, viz. the extension of a piece of the iris and the detachment of the iris from the ciliary ligament, as practised both by Schmidt and Scarpa. But, according to Beer, all violent pressure, or actual contusion, particularly when it affects the portion of this organ between its two circles, cannot be borne even in the best constitutions, and the least grievous consequence is inflammation, soon followed by a partial, or complete closure of the pupil, or suppuration in the eyeball. When the instrument causing such injury passes to the iris through the cornea, as is mostly the case, and the wound in the latter tunic is extensive, the torn iris is frequently pulled between the edges of the wound, at the moment when the weapon is withdrawn, and protrudes in a lacerated state. In this case, Beer recommends the torn projecting piece of the iris to be cut away with scissors close to the wound in the cornea, when the rest, he says, is generally retracted within the eye.

Thus an adhesion of the iris to the cornea, termed *synechia anterior*, may often be prevented, which, when the lacerated iris is suffered to hang out of the cornea, is inevitable, surrounded by a large opaque cicatrix.

Some violent blows on the eye, though they cause no wound, are attended with such a concussion of the anterior hemisphere of the organ, that more or less of the iris is instantaneously separated from the part of the ciliary ligament, where the force is most vehement. The consequence of this accident is either a double pupil, or the natural pupil closes, and the artificial one remains open. Such injuries may be produced by the lash of a whip, or a horse's tail (a common accident in the narrow streets of Vienna), or the thrust of any bluntish weapon against the outer part of the cornea; and they are purposely inflicted in the method of forming an artificial pupil, recommended both by Schmidt and Scarpa.

Wounds, which enter the eye through the sclerotic near the cornea, usually produce a considerable effusion of blood in the chambers of the aqueous humor; but, Beer thinks, that there is never any necessity for making an opening for its discharge at the lower part of the cornea, except when it is so considerable as completely to hide the iris; and at the same time that the eyeball is affected with very painful tension and hardness.

Wounds of the eyeball, affecting the corpus ciliare, are set down by Beer as extremely dangerous, independently of the inflammation which quickly follows. However, such injuries are most serious when they consist in a real contusion, or laceration of the corpus ciliare, which can hardly take place without a severe concussion, or actual disorganisation of the retina, and laceration of the principal ciliary nerves and vessels. Hence, besides an effusion of blood in the chambers of the aqueous humour, a partial or complete amaurotic blindness is instantly produced, and the iris, in the vicinity of the place where the instrument entered, is so retracted towards the margin of the cornea, that neither of its circles can be seen. In cases of this description, it also frequently happens, says Beer, that the patient, or the person who inflicted the wound, suddenly and roughly pulls the weapon out of the eye again, and together with it a part of the corpus ciliare, which is then to be regarded as an extraneous substance, and to be immediately cut off. With respect to the prognosis and treatment, the observations already made on these topics, in reference to wounds of the iris, are here quite applicable; excepting that the effused blood is less copious than in the latter cases, and therefore there can never be any necessity for letting it out by a depending opening in the cornea.

Wounds of the eye, affecting the crystalline lens, are not unfrequently followed by the formation of a cataract, and so are blows on the eye, which may be supposed to produce this effect by destroying some of the minute nutrient vessels naturally connecting the capsule with the lens. (Beer, b. i. p. 218.) The treatment of these accidents resembles that of injuries of the iris, except that the surgeon has rarely any extravasation of blood to deal with. However, when the lens has slipped into the anterior chamber, Beer recommends its immediate extraction through an incision in the cornea, in order to prevent the eye from being destroyed by a violent attack of traumatic inflammation and suppuration.

Nor, when inflammation has come on, should this measure be postponed, as Beer has constantly found the disorder lessen after the lens has been taken out.

Considerable wounds of the eye, attended with loss of the vitreous humor, are described by Beer as of a very serious nature; but, they rarely take place accidentally, being almost always the consequence of a surgical operation. Accidental injuries of this kind are generally combined with so large or complete a discharge of the vitreous humor, and with such mischief to the organisation of the eye, that the consequence is a loss of the eyeball, or such a dwindling of it, that the fissure of the eyelids becomes nearly closed. According to Beer's experience, injuries of the foregoing kind, arising from accident, are mostly produced by the horns of cows. On the contrary, the effusion of the vitreous humor in operations upon the eye, he observes, is seldom followed by the loss of vision. See CATARACT.

Considerable injuries of the eyeball, complicated with a concussion, bruise, or actual wound of the retina, produce, either gradually or immediately, an amaurosis, which is almost always incurable. When the concussion of the retina is less violent, and does not affect every part of this texture, it may occasion only an amaurotic weakness of sight. In worse cases, the surgeon may think himself very successful if he can prevent the figure of the eye from being destroyed by the subsequent inflammation, all idea of the recovery of the eyesight being out of the question. The treatment is the same as that commonly adopted after operations for the removal of an opaque lens (see CATARACT); but there is one particular circumstance, sometimes attending injuries of the retina and ciliary nerves, claiming notice, viz. violent vomiting; a symptom which Beer says may even attend contusions of the sclerotica and of the ciliary nerves and retina, without any wound. Injuries of the ciliary nerves, he observes, are denoted by a very peculiar appearance; for, near the injured part, the iris is drawn up so close to the edge of the cornea, that its colour can scarcely be seen. When the surgeon is consulted in a case of this kind, though some inflammation may have commenced, the prognosis is yet favourable in regard to the preservation of the eye; for a gentle opiate will relieve the vomiting when merely a nervous effect, not depending upon the loaded state of the gastric organs; but, if the case be of this last description, the primæ viæ should first be emptied. However, when a traumatic inflammation is completely established before the treatment is begun, the eye is generally destroyed, as the repeated and violent vomitings cause a great determination of blood to the head and eyes, and increase of the inflammation; an effect, which the opiates, given for the relief of the vomiting, also tend to produce.

Beer has seen two cases, in which the eye was pricked with a needle near the insertion of the external straight muscle into the sclerotica: in both instances, the punctures were so small, that they would scarcely have been found, had not the patients known their situations exactly by the pain, and they were then only perceptible with a magnifying glass. The punctures were soon followed by a convulsive rolling of the eyeball, and afterwards by trismus, which continued severe in one patient a day and a half, and in another two days, but yielded to large doses of musk and

opium given at short intervals, the warm bath, and the application of warm poultices containing hyoscyamus.

As chemical injuries of the eye produce an actual loss of substance, they are even more serious than common mechanical lesions. However, chemical injuries of little extent are generally repaired with tolerable facility and expedition. Quietude of the organ, and moderating the outward noxious effects by lukewarm mucilaginous applications, either in the form of fomentations, or eye-waters, are the only requisite measures. If the cornea itself be hurt, as frequently happens, when boiling hot fluids strike the eye, a kind of vesicle appears on the injured part, which becomes more and more white. The vesicle either bursts of itself, or subsides without breaking. In both cases, the production of the conjunctiva, of which the cyst of the vesicle is composed, shrivels up, and peels off, a new membrane of a similar nature being regenerated underneath. An opaque speck is frequently apprehended; but, says Beer, if the surgeon will merely avoid being too much in a hurry to open the vesicle, and not disturb the work of nature by applying various remedies to the eye, there will be no danger of such an occurrence.

More extensive chemical injuries of the eye, which at first are not in themselves very severe, frequently become dangerous, in consequence of care not being taken to prevent the influence of external stimuli. To this class of cases belongs the accidental sprinkling of the eye with boiling fluids or strongish mineral acids. And even in these examples, says Beer, the prognosis is not unfavourable, and a complete recovery may be effected when the treatment is conducted according to the directions already given with respect to such accidents in general. While this author approves of cutting away any substance which is dead and partially detached, he strongly cautions surgeons not to remove the thin layer of the conjunctiva, nor to puncture any vesicle which may form.

When the burning, or corrosion, is not limited to the conjunctiva of the eyeball, but extends to the lining of one or both eyelids, Beer recommends covering the injured parts with mucilaginous applications and mildly astringent ointments containing putty or the white oxide of lead. In these cases, keeping the eye perfectly motionless must be hurtful, as it tends to promote the formation of adhesions, either between the eye and eyelids (Symblepharon), or between the eyelids themselves (Ankyloblepharon).

Extensive, deeply penetrating, chemical injuries of the eyeball, are almost always followed by impairment of the functions of the organ, or of some of its particular textures, because such accidents never happen without a loss of substance. Thus a part, or the whole, of the cornea, may be entirely destroyed, as in injuries caused by quicklime; and frequently adhesions between the eye and eyelids, or between the two latter parts, cannot be prevented by any kind of skill. (Beer.) These serious degrees of mischief, as the same author observes, are mostly occasioned by slaked, or unslaked lime, concentrated mineral acids, fire, &c. Unslaked lime, especially when extensively diffused over the eye by the immediate application of water, not unfrequently produces a sudden destruction of the whole of the cornea, which is

changed into a greyish pappy substance, capable of being removed from the subjacent iris with a camel-hair pencil. Such an annihilation of texture, however, is generally restricted to particular points, or the surface of the cornea. Wherever this membrane has been so much decomposed that a manifest depression is directly preceptible in it when inspected sideways, a snow-white shining speck must be expected to be the consequence. Slaked lime never operates upon the cornea with so much violence, usually causing (as Beer states) only a superficial corrosion, or a coagulation of the lymph between the layers of the cornea. Nor are mineral acids, even when concentrated, generally so destructive to the cornea as quicklime: first, because, as fluids, they do not long remain in contact with the eye, and secondly, because the immediate mixture of the tears with them weakens their operation, whereas it only increases that of unslaked lime. The local treatment here consists in carefully removing every particle of the hurtful substance, afterwards dropping frequently into the eye lukewarm mucilaginous decoctions or collyria, or covering the injured place with a mild cerate, and excluding the air and light from the eye. Every endeavour must also be made to prevent the formation of adhesions between the injured surfaces.

In severe burns of the eyeball, of course all idea of restoring its functions is out of the question. The violence of the injury is the greater, the more numerous the vesicles are upon the conjunctiva, and the more the eyeball and the iris are incapable of motion. Here the only indication is to moderate the inflammation, and avert such additional mischief, as might otherwise be produced by it. With this view, the eye should be kept at rest, and excluded from the light and air. According to Beer, the most common injuries of the eye, partaking both of a mechanical and chemical nature, are those caused by mortar, or the accidental touching of the eye with hot irons. When the mortar contains no particles of quicklime, it often occasions, at particular points of the cornea, very white specks, which Beer describes as being composed of coagulated lymph, and admitting of dispersion. He even declares, that when the whole of the cornea is in this state, its transparency may be restored by proper treatment, as has been frequently exemplified to the gentlemen attending his clinical lectures. (B. i. p. 234) The pricking of the eyeball with a red-hot needle, and the stinging of it by bees, wasps, and other insects, are also both chemical and mechanical injuries. Whether the sting be left in the skin of the eyelid, or in the conjunctiva, or not, a considerable inflammatory swelling immediately takes place; and if the sting be lodged, and not now taken away, the inflammation spreads, and the eye itself is endangered. In two cases where the stings of bees were left in the skin of the upper eyelid, Beer knew gangrene arise, and the patients were saved with great difficulty. The treatment of such cases consists in immediately extracting the sting, if lodged, and applying folds of linen over the eye, wet with cold water.

After noticing the destructive effects of burning substances, the explosion of gunpowder, and fulminating silver, on the eye (cases in which, when the functions of the organ are annihilated,

the only indication is to diminish the subsequent inflammation and its consequences), Beer inquires, what is the reason why the slightest mechanical, or chemical, injuries of the eye, in an apparently healthy subject, are sometimes followed by an immoderate degree of inflammation, and even the loss of the organ from suppuration? It is, says he, an observation made by Schmidt, that there are some eyes which the greatest bunglers may abuse for hours at a time without being spoiled, their powerful organisation defying all such unskilful disturbance; while other eyes are met with, which the most skilful operators can hardly touch without inducing a destructive degree of inflammation and suppuration. It was to this peculiar idiosyncrasy that Schmidt applied the term *vulnerability*. (*Verwundbarkeit*.) Patients of this habit are said to possess an exceedingly fine soft skin, with a reddish polish upon it; and their cheeks are not only red, but exhibit a network of very minute vessels, which seem as if injected. Such individuals appear as if they were in the bloom of health: and, says Beer, in some respects they are really so. When their spirits are raised by the slightest causes their complexion is universally reddened; but the least fear turns them pale as a corpse. Their skin is uncommonly irritable, sensible of every impression, and attacked with an erysipelatous redness, whenever any fatty substance touches it. In such habits the utmost caution is necessary whenever the eyes have been injured, and the prognosis should be reserved.

Spasmodic twitching of the eyelids.—This is commonly the effect of intestinal irritation, especially that produced by ascarides; and a purge, followed by a little tonic medicine, quinine, or iron, suffices to put an end to the annoyance.

Injuries of the eyelids. Ecchymosis.—The best mode of treatment consists in the application of a poultice formed of the scraped root of black bryony mixed with linseed meal or bread crumbs. This produces a stinging sensation in the skin, and effects a very speedy disappearance of the effused blood.

Emphysema of the lids arises from blows; blowing the nose puffs the eyelid up. The swelling is unattended with any redness of the skin, and, on pressing the part with the fingers, the surgeon at once perceives the peculiar crackling of air effused into areolar tissue. The cause of this emphysema

is rupture of the lining membrane of the nose, with fracture of the lachrymal, or perhaps of the ethmoid bone; and until the fissure has closed, the emphysema is apt to recur if the patient blows his nose. If he abstains from this the effused air soon becomes absorbed without any especial treatment. (*Dixon, A Guide to the practical Study of Diseases of the Eye, &c.* 1855, p. 288.)]

FEVER. [In this Dictionary we are not called upon to treat of the various kinds of fever which custom has assigned to the care of the physician; such as the agues, and the malarious and remittent fevers, which are believed to arise from marsh emanations; the continued fevers, including the typhoid, typhus, gaol fever, plague, and others, which are believed to arise from mismanagement of the conditions under which human beings live; nor yet of those mysterious epidemics, or influenzas, which are believed to be brought by the wind; nor yet of the exanthematous class, as the small-pox and scarlet fever, which, as a rule, attain their full development but once in the lifetime of any individual, and which are supposed to be produced by some specific contagion.

In this place we propose to treat generally of those fevers, or feverish conditions, which may accompany such local inflammations, wounds, and injuries, as the surgeon is accustomed to consider his special objects of study.

Using the word fever in this sense, we mean by it a general disturbance of the whole faculties and functions of the body, beginning usually with shivering followed by increased heat and dryness of skin, lightness or pain or confusion of the head, aching and lassitude of back and limbs, weakness and incapacity of mental and bodily exertion, disturbed action of the heart and arteries and lungs, and interruption or disorder of the secretions of the tongue, intestinal tube, kidneys, and skin.

These disturbances are capable of a truly infinite variety in kind, in degree, and in mode of combination; sometimes so violent as to extinguish life rapidly, sometimes so slight as to be scarcely noticed, and sometimes almost indefinitely prolonged.

The climax of severity is found in that febrile condition which may be called intense surgical or traumatic or hospital fever, which is identical with acute pyæmia, and with the worst members of the erysipelatous alliance. The slightest grades of surgical fever, vary from the condition called *hectic* to that commonly called *cachexia*. In the one extreme of the series the fever may be a foudroyant

attack that prostrates the body like a cannon ball, and destroys life in a few hours; in the other, a slight chilliness and languor, which may go on for months or years.

Fevers, or feverish maladies, such as those which we have to do with, have a twofold, sometimes a threefold, relation to local disease.

In the first place, the starting point may be local. Some change in the tissues of an injured part, some irritation of the nerves of sensation, or some change undergone by the fluids at one point, possibly by the imbibition of a poison, serves as the first step in the chain of morbid phenomena, and seems to change the composition of the whole blood, and so irritate the whole system. This is the case in the symptomatic or sympathetic fever which accompanies an irritated or ill-treated wound.

Secondly, the changes in the blood and nervous system instead of being secondary may be primary, and may be the originating cause of idiopathic local inflammation. Instances of this are so common as to require no illustration; yet we may refer to the well-known cases of the exanthemata, of idiopathic erysipelas arising from infection, or from bilious disorder, of boils, and the like.

Thirdly, a febrile condition having been excited by local change, may be the parent of secondary (*consecutive* or *metastatic*) inflammations in other remote parts. Pyæmia and glanders are examples.

These relations of *general febrile* with *local inflammatory* changes are, besides, often combined in different ways in different cases of the same disease. Thus, erysipelas may begin by local contamination of a wound; so notoriously may hospital gangrene; so does the small-pox when inoculated; so may some cases of farcy, of puerperal fever, and of the diffuse inflammation; whilst, in other cases of these same diseases, the first step is no local change, but a general malaise and shivering, which perhaps precede any local changes by some hours or days. In other cases, again, as in snake bites, the first local change, and the general blood infection, come at one *coup* from one and the same cause, and it were idle to talk of either preceding or being the cause of the other.

The general law appears to be, that the local changes are, as the Germans say, *the localisation of the blood crisis*; or, in plain English, that whereas the entire mass of blood and serum is one fluid, every part of which is miscible with every other part, so any perverted portion of blood or serum may be absorbed into and taint the whole, and so any morbid matter in the whole may be exuded into any particular part.

We do not pretend to give any thorough or satisfactory explanation of the phenomena of fever, or of the changes which take place in the course of it; still less will we wander into the region of *final causes* or purposes, which seems to have such a dreamy charm for the idolators of John Hunter. But, regarding as we do an hypothesis to be an allowable mode of giving the best explanation of any given set of phenomena, compatible with the present state of knowledge, we may give the following as our hypothesis of fever, whether in the general sense, or in that more limited sense in which it interests the surgeon:—

“A process of decomposition set up in the blood, and producing increased oxidation, or local deposit, or increased secretion, or all three.” (*Surgeon's Vade Mecum*, 8th ed. Lond. 1859, p. 27.)

This definition, or quasi definition, purposely includes the feverishness produced by a debauch, by over-fatigue, or by inhaling putrid vapours, or any specific poison; and it includes most of the cases which come under the term cachexia, which really seem to differ from fever solely in the slowness, or, we might almost say, the perpetuity, of some of them. That the causes of cachexia may be hereditary, or derived from remote disorders of assimilation, is no sign of difference in the processes, all of which may be included in our formula.

Before proceeding further, we may remark upon the strange controversy which occupied the attention of our forefathers, when they disputed whether there could be such a thing as *essential* or idiopathic fever (*i.e.* fever dependent on blood disease or other general disorder), or whether all fever was not dependent upon local disease, being itself an "irritation" of the constitution consequent thereupon. The kind of argument was this: Local inflammation excites general fever; therefore, all general fever is excited by local inflammation. In accordance with this doctrine, some believed typhoid fever to be an inflammation of the brain, or lungs, or intestines; some believed the cold stage of ague to be caused by congestion of the heart, &c. This false doctrine was supported, moreover, by the results of post-mortem examination, for the local congestions discovered after yellow fever, for instance, were assumed to be the cause of the general symptoms. Pathologists of this school resembled the Brahmin philosopher, who put the earth on an elephant, the elephant on a tortoise, and so on, without reflecting that the putting off a difficulty is no solution of it.

The more liberal and comprehensive pathology of the present day enables us to escape the difficulty of having to choose between two seemingly opposite theories by accepting them both, because each is true under certain circumstances. There are cases in which, by allaying local irritation, feverishness disappears like magic. There are, again, other cases in which local medication is absurd, or impossible, or injurious, and in which "attention to the general state of health" will remove the local symptoms without difficulty. There are others in which both sets of treatment are required; but be this as it may, the local and the general symptoms are parts of one and the same thing, and cannot be dissociated in practice. To treat the feverishness which accompanies erysipelas, apart from the erysipelas, is impossible. Let us now briefly consider the varieties of febrile disorder which accompany local disease, whether as cause or effect. They are—

1. The Common Symptomatic, Sympathetic, Traumatic or Inflammatory fever.
2. The Irritative or Pyæmic.
3. The Acute Hectic, and the Common Hectic or fever of exhaustion, and Cachexia.
4. The Putrid Typhoid type, arising from the absorption of putrescent matter.]

[I. SYMPTOMATIC FEVER. This will be minutely described, according to modern ideas, in the Art. INFLAMMATION, to which it properly belongs. Here we shall content ourselves with reproducing, as part of the history of medicine, some of the older doctrines found in the works of Hunter, and recorded in former editions of this Dictionary.]

Every local complaint of any consequence, says Hunter, or which has considerable and quick ac-

tion within itself, although not of considerable magnitude, affects more or less the constitution, and gives rise to what has been called the symptomatic fever. These symptoms are the sympathies of the constitution with a local disease or injury, and will vary according to many circumstances, such as the age, the quantity and manner of the mischief done. Such fever, Hunter believed, if an injury were considerable, to be a natural result, and a much better sign of health than when no fever takes place. Nature, he says, requires to feel the injury, for where after a considerable operation there is rather a quiet, weak pulse, often with a nervous oppression, with a seeming difficulty of breathing, and a loathing of food, the patient is in a dangerous way. Fever shows power of resistance; the other symptoms show weakness and sinking under the injury.

In spontaneous inflammations, says Hunter, it is not easy always to know whether the constitution or the part is first affected; the priority of symptoms is a guide, although the constitutional symptoms are often so slight as not to be taken notice of.

Sympathetic inflammatory fever, he continues, is the sympathy of the constitution with the first stages of a local disease, which excites an alarm in the constitution, thereby rousing up its powers to produce succeeding actions.

[So far as Hunter writes from observation of disease, his sagacity is marked. But his reasonings are obscure and self-contradictory; his attempts at finding motives for morbid phenomena usually unhappy, and the conclusions derived therefrom erroneous. He spoke of *action* and *sympathy*, where we speak of chemical decomposition of the blood; he always tended to lose sight of plain facts in the search for final causes; and so spoke of fever as a necessary and beneficial process, whereas it is unnecessary, intrusive, and mischievous. We now consider fever, like inflammation, to be a disease and a complication of injuries, and not a beneficial process, although we still continue to speak of a *healthy* inflammatory fever, by way of contrast with other cases which are more unfavourable, and more unhealthy.]

The following extract from Mr. Travers will serve to show the doctrines entertained by our forefathers on the subject of fever, as arising from irritation:—]

"It is scarcely necessary to illustrate the influence of an irritable temperament upon the consequences of casual injury or disease. Practically, we all know it well. We say, *such a person would be a bad subject for a compound fracture*; and whoever has had opportunities of watching several subjects of compound fracture under treatment at one and the same time, well knows the import of this phrase, and that the greatest degree of mischief is often accompanied by the least constitutional disturbance, and, for this reason, is soonest and most perfectly restored. The first few hours will enable an experienced observer to determine whether the subject of a serious injury or operation will do well or otherwise. How vastly different in different individuals is the inconvenience attending such minor derangements as a boil, an enlarged gland, a whitlow, or a simple ophthalmia. In some, the constitution seems ignorant of the affair, and the individual pursues his ordinary occupations. In others, the whole system sympa-

thises; the spirits are ruffled; the nights are restless; the appetite fails, the pulse acquires an undue bound; and the white tongue, the creeping chilliness, and slight erratic pains of symptomatic fever are present." (*Travers on Constitutional Irritation*, p. 15.)

We may set down the ordinary symptoms of inflammatory fever, occurring in consequence of local inflammation in common parts, and in a healthy habit, as follows:—The pulse is frequent, full, and strong; all the secretions are diminished; the patient is vigilant and restless; the perspiration is obstructed, and the skin is hot and dry; the urine is high-coloured, and in small quantity; the mouth is parched, and the tongue furred; an oppressive thirst is experienced; with disturbance of the nervous system; loss of appetite and sleep; and, in some cases, delirium.

As Dr. Thomson has remarked, "the inflammatory fever, succeeding to external injuries, or to surgical operations, undergoes a kind of natural crisis, by the appearance of suppuration. In these instances, therefore, unless when the patient is strong and in full health, when the disease is seated in an organ of much importance to life, or is in danger of spreading, as is the case in all inflammations of the membranes lining the three great cavities of the body, the lancet ought to be used with caution. For we may, by too free a detraction of blood, produce a sudden sinking of the powers of life, and convert the existing constitutional symptoms into fever of a different type or character. But, in all cases of inflammation, in which any doubt arises with regard to the farther general detraction of blood, it may, I believe, be laid down as a general rule, that it is safer to employ local than general blood-letting." (*Lectures on Inflammation*, p. 170.)

Here we leave the subject, referring our readers to Art. INFLAMMATION for the modern views.]

[II. IRRITATIVE OR PYÆMIC FEVER. Under this designation we include the sum of the constitutional symptoms which accompany the class of local inflammations of which erysipelas and diffuse inflammation are types. It corresponds strictly with the irritative fever of Butter, and the constitutional irritation of Travers.

It was evidently considered by Travers, and the other writers of that generation, that fever, *i.e.* symptomatic fever, was a normal consequence of injuries in healthy persons; but that, under certain depressing circumstances, the symptoms displayed were not those of fever, but of acute constitutional irritation, arising from the action of an injury or poison on the nervous system. At that day, humoral pathology was in abeyance, and solidism reigned undisturbed. *Direct* irritation was the term used to signify the primary effect of the injury or poison; *reflected* irritation, the effects of the changes which it subsequently set up in the blood.

The symptoms of irritative fever, using the word to signify the constitutional symptoms of pyæmia and diffuse inflammation, are thus summed up by Mr. Travers:—"Rigors, nausea, and retching, abdominal tension, restlessness, and depression of spirits, with a rapid and feeble pulse, coated tongue, pinched countenance, partial perspirations, and, at length, delirium, followed by stupor and laborious breathing." (*Constitutional Irritation*, p. 276.) The presence of inflammation, continues Mr. Travers, is an indication of power, and implies that

the nervous system is unexhausted. Pain and fever are incompatible with the state of high prostration. The pulse of real fever does not exceed a certain limit, and that consists with the property of distinctness; when it is innumerable, and from that cause indistinct, it ceases to be fever.

Rigors followed by increased heat, sometimes by profuse and fetid perspirations; action of the heart more rapid, tumultuous, and oppressed, than in common symptomatic fever; pulse jerking and soft, and from 120 to 160 or more; breathing rapid, that is from 30 to 40 or more per minute; nervous system variously affected: sometimes the mind quite clear; some sleep, if there be no local pain; sometimes delirium; later, stupor or coma, with twitchings or jerkings of the limbs: in some cases great irascibility and snappishness; hiccough, oppression at the region of the heart, and faintness; the bowels sometimes the seat of eliminative efforts; putrid, or bilious, or offensive motions, or redness of tongue, with aphthæ; in most cases tongue coated, dry, and white, or moist and yellow; at a later stage dry and black; nausea, retching, and vomiting very frequent; urine variable. Such are the symptoms.

These symptoms admit of classification in various sets of cases, and the best is that proposed by Dr. Ferguson, in his work on puerperal fever, with which this malady, as seen in the surgical records of hospitals, is perfectly homologous, if a wound or injury be substituted for a recently emptied womb. The first form is that in which local symptoms at the seat of injury preponderate, as in the peritoneal form of puerperal fever, or in cases of Irritative Fever, related Art. ERYSIPELAS, or in the following description of phlebitis after venesection, from Mr. Travers:—

"Moderate swelling, but great tension of the limb, and cordy hardness of the vein, traceable towards the axilla; insupportable pain, sense of weight and immobility, with a festered or oozing state of the orifice, are local symptoms; but the extreme constitutional excitement, morbid vigilance, mental irritability and despondency, partaking more of the nervous than of the simple inflammatory type, is peculiar. The blood drawn is strongly cupped and buffy. The pulse, rapid and stringy, becomes more full and soft after copious depletion, but the pain is only partially relieved." Surgically speaking, the safety of a patient in such a state will depend on free incisions. (See ERYSIPELAS AND DIFFUSE INFLAMMATION.) Besides the danger arising from enormous suppuration in loco, affecting probably the veins and lymphatics, there is that of secondary abscesses into the joints or viscera.

The second form, says Dr. Ferguson, assumes the character of mild typhus, with intestinal irritation. After a rigor and hot fit, there is marked irritation of the mucous membrane of the intestinal canal, either vomiting, nausea, or diarrhœa, in which the evacuations display every shade and degree of colour and consistence. The tongue, at first loaded and white, soon becomes preternaturally red. The skin is dry, hot, and dusky yellow; the mind is unsettled, without being absolutely delirious, and the impressions on the eyes are unwontedly vivid; the debility extreme, and the limbs tremulous. This form, if it terminates fatally, probably does so by purulent deposits, as the former does.

The third form is marked by anomalous nervous symptoms; extreme terror and depression; sudden and death-like faintings; sighing, tremors, and cramps—as in the case of Mr. Elcock, who died in forty hours after the receipt of a puncture in dissection, with *no local symptoms*, but with all the violent and alarming excitation of the nervous system peculiar to hydrophobia. (*Travers, op. cit.*)

The fourth form is the ataxic, or that in which local deposit in various organs defies all calculation, and, too often, all remedy. Extreme prostration; a rapid pulse; a skin dry, or offensively perspiring; a dusky red patch on the cheek; “a dull, glassy eye, encircled in leaden lids;” oppressed and sighing respiration; mind calm, and often wonderfully unconscious of danger. Such are the general symptoms which attend those pyæmic states, of which rapid effusion into, and disorganisation of, the eye, brain, joints or viscera, are the usual and fatal consequences. (See ERYSIPELAS, ABSCESS, PYÆMIA, POISONED WOUNDS.)

The treatment will be found under the articles just quoted.]

[III. **HECTIC.** *Acute hectic* is a constitutional condition for which the surgeon may be consulted, and in which he may have to rely on his own sagacity for the detection of the local cause.

As we observed in the article ABSCESS, *shivering* is an accompaniment of most blood changes. It occurs at the beginning of fever and inflammation, for instance. But there is another kind of shivering, which may occur in the *course of* an inflammatory attack, and which indicates that pus is being absorbed from the seat of disease.

It is often stated in surgical books that rigors are a sign of suppuration. This is not true in a general sense; on the contrary, suppuration may occur without rigors; but they occur when the pus under certain circumstances, not having vent, is absorbed into the blood; and they constitute the first state of acute hectic.

We define, then, the acute hectic, to be a fever having daily paroxysms, and depending on the absorption of decomposing pus.

The symptoms are usually these. A patient, who has some concealed abscess, or who has an abscess which is not opened, or which if opened does not thoroughly discharge itself, is seized with violent shivering, exactly resembling, and probably quite as severe as the cold stage of an ague. The most remarkable case which the writer ever saw is that of a lady with ovarian disease of thirty years' duration, who was suddenly seized with shivering, the commencement of a fatal illness; so severe was it that she was quite unable to move from her chair to the other side of the room to ring for assistance. It is attended with blueness of the nails, shrinking of the fingers and all the other signs of ague. To this follows a hot fit, with flushing, headache, and thirst: and to this, a sweating fit; the hair and skin and bed-clothes being soaked in a clammy, offensive perspiration, which goes off, leaving symptoms of extreme debility.

The time at which the writer has observed these symptoms to come on, has been from four to six P.M.; and they last from eight to ten hours in well marked cases. During the day, paleness, and quickness of the pulse and languor remain. If the case goes on, the next symptom is a cleaning

of the tongue, the epithelium of which becomes thin, so that it looks like a dog's tongue, or even redder. To this follows a tendency to diarrhoea; and frequently very decided attacks of that malady, with mucous and bloody evacuations. Meanwhile the appetite fails: sleep is lost: the hair falls off, emaciation increases, and unless the local cause be removed, the patient either passes into the state we call the *Typhoid-like* or *Sulphide-of-Ammonium-in-the-blood-stage*, or else sinks exhausted.

That these symptoms arise from the absorption of deleterious matter from abscesses and the like, is evident, partly from the facts of the case and from analogy; partly from the instant relief afforded when the abscess is opened, or other means taken to remove the cause. (See *Case, Art. ABSCESS*, p. 8.)

Whenever such symptoms present themselves, therefore, the surgeon is bound to make the most diligent scrutiny for some local cause which can give rise to them.

Nevertheless, Hunter and his followers denied that the absorption of pus gave rise to hectic; because, said they, much pus is absorbed without hectic. “If,” he says, “the absorption of matter always produced the symptoms above described, how could any patient who has a large sore possibly escape hectic? for there is no reason to suppose that one sore can absorb more readily than another. If absorbed matter occasioned such violent effects as have been commonly ascribed to it, why does not venereal matter do the same? We often know that absorption is going on, by the progress of buboes. A large one, just on the point of bursting, has been known to be absorbed, in consequence of a few days' sea-sickness. The person continued at sea for four-and-twenty days afterwards; yet no hectic symptoms followed, but only the specific constitutional effects, which were of a very different description.”

To this the reply is simple. It is not pretended that the absorption of pus *simpliciter* will cause hectic; but of pus, and of other substances in certain states of decay. This is well illustrated by a case put by Hunter himself. He says that in large chronic abscesses the hectic seldom comes on until after they have been opened, although they may have been forming matter for months. But in such cases the disposition often comes on soon after opening.

The fact is, that after the opening of a large and incurable abscess absorption of matter may take place, which has been partially decomposed by exposure; and which may produce hectic now, though not in its undecomposed state.

The Hunterian theory was that hectic depends on the parts being stimulated to produce an effect which is beyond their powers; that this stimulus is sooner or later in taking effect, in different cases, and that the constitution becomes affected by it: “The universal sympathy with a disease which gives the irritation of being incurable;” “the constitution irritated with an incurable disease;” or “harassed with a disease where the parts have no power, or, what is more probable, have no disposition to produce a salutary inflammation and suppuration.” These are various explications, in which the solidism of Hunter appears conspicuously.

Common or Chronic Hectic. Under this term we are obliged to include almost all the con-

stitutional symptoms of all the diseases that wear out life by a process of slow exhaustion, and which are attended with chilliness and accessions of fever.

In the first place, there are the cases in which incurable local disease is the main cause of the hectic: such as disease of joints, necrosed bone, and the like. In these cases there may be some absorption of pus; or it may be merely the continued influence of pain and sleeplessness; of bad appetite, and bad digestion; of want of air and exercise, which bring the patient to the extremity of weakness.

In the next place, hectic may arise from some blood changes, which are the result of bygone morbid influences, and are the parents of local disease. Thus in the early stage of phthisis, in disease of the kidney, in secondary syphilis, in subacute periostitis, in various forms of dyspepsia, reiterated attacks of febricula occur, consisting of evening chills, followed by flushes, hot skin, quick pulse, and night perspirations. There is no doubt whatever but that these hectic symptoms may exist, either in incipient cachectic disease, or in prolonged disease, without being caused by absorption of pus.

Nevertheless, the writer believes that in cases in which the hectic character is the most strongly marked, in which the paroxysms are most regular, the pulse quickest, the tongue red, and the bowels most irritable, that there an absorption of pus is most probable.

For example: The writer is at this moment attending a gentleman in the early stage of phthisis. There is some morbid deposit in the upper lobe of each lung, some cough, and some muco-purulent expectoration; but judging by analogy, no ground for assuming absorption of pus more than there would be in every case of catarrh. Moreover, the pus is not offensive. This patient has had several attacks of febricula, *i. e.* evening chills and profuse night perspirations, but they come irregularly, and although attended with diarrhoea, it is not severe.

On the other hand, the writer was lately attending an aged lady with epithelial cancer of the womb. As the disease advanced, the discharge became more offensive and profuse, and the ulcerated surface larger. On a sudden, one day her bowels became irritable, and her tongue, from being of the ordinary colour, was observed to have lost its epithelium, and to be red as a dog's tongue. This condition, with evening paroxysms of restlessness, lasted till her death.

In the former of these cases, we assume that the hectic arose from malassimilation or tuberculosis, and indicated deposit: in the latter, that it indicated absorption of decaying pus.

The *symptoms* of common hectic are evening chills, followed by heat, thirst, and restlessness, and by profuse perspiration. The perspiration generally begins soon after the patient has dropped asleep, and wakes him up. It is profuse, often offensive. The urine loaded with red sediment.

To these are added many signs of wasting and debility. The hair falls, the finger nails chip, the teeth decay; (although the theory has been broached that caries of the teeth is a preservative against phthisis); the skin is harsh and withered, and there is a general air of languor. The state of the appetite depends upon circumstances. In some cases, in which the digestive organs are not pri-

marily or secondarily involved, the desire for food is immense, and digestion amazingly rapid. In others, in which diarrhoea prevails, all food may be loathed. The state of the bowels too is usually loose, but not unfrequently scrofulous ulceration of the mucous membrane comes on, and then there are attacks of the severest pain, with bleeding, and that intolerable fœtor of the motions which ensues when blood is mixed with fœcal matter and has time to decompose. Death, in these cases, usually occurs by asthenia; the patient faints away, and never recovers.]

[IV. The PUTRID or TYPHOID TYPE of traumatic fever, is that which is caused by the absorption of truly putrescent matter, probably of the sulphide of ammonium.

John Hunter, who may always be depended upon when he describes what he has seen, devotes a section of his work on the Blood and Inflammation to what he calls *dissolution*, or the manner in which death occurs after external injuries. He says that it may occur at any stage after an injury; sometimes appearing to be a continuation of the sympathetic fever, sometimes following a protracted suppuration and hectic. A man, he says, shall lose his leg, or suffer a bad compound fracture, and the earliest symptoms shall have subsided, and all seem to be going on well, "when suddenly he shall be attacked with a shivering fit, which shall not perform all its actions, *viz.* shall not produce the hot fit and sweat, but shall continue a kind of irregular hot fit, attended with loss of appetite, quick low pulse, and sunken eyes, and the person shall die in a few days." "Or, if the local disease does not or cannot heal, and is such as to affect the constitution, it then brings on the hectic, and sooner or later dissolution takes place."

The symptoms, according to Hunter, are shivering and vomiting, oppression, anxiety, and expectation of death; quick small pulse, perhaps bleeding from the whole surface of the sore; often mortification, with every sign of dissolution in the countenance.

This disease also, he says, has been supposed to arise from the absorption of matter. It is apt to follow violent and long-continued inflammations and suppurations, particularly of the lower extremity; it takes place more readily in hospitals than in private houses, and in cities than in the country. It is liable to follow amputation of the leg, and cutting for the stone in fat men who have lived well; and appears, according to Hunter, to be a thorough failure and abandonment of vital power. Hectic and "dissolution," he adds, are by no means the same disease; and that hectic may generally be relieved if its cause be removed; whereas "dissolution seems more to be connected with the past than the present;" that is, to be the result of foregone and irremediable exhaustion.

It is easy to recognise in Hunter's description some cases of pyæmia, perhaps some of hospital gangrene; and above all, the condition which we now proceed to describe.

Suppose a large chronic abscess, which has been opened; the sac has bled, the pus has putrified. Now come shivering, a hot skin, dusky complexion, dry brown tongue, sordes on the teeth, and weak, fluttering pulse. The ulcer or sac ceases to suppurate, but oozes a scanty bloody serum. The bowels are probably loose; the nervous system is

profoundly disturbed; low muttering delirium, twitching, and the other well-known symptoms which usher in death.

That these symptoms arise, not from exhaustion, as Hunter thought, but from poison, was distinctly believed long before Hunter, but was proved experimentally by M. Bonnet of Lyons, in a paper published in the *Gazette Médicale*, and translated in the *London Medical Gazette* for 1837, (vol. xxi. p. 490, *On the absorption of pus which has been in contact with the atmosphere.*)

M. Bonnet shows that the fœtor of putrid pus depends on the presence of sulphide of ammonium, which cannot be detected in it by ordinary tests, because the presence of albumen sets at nought all the ordinary metallic reactions. The same with the blood and urine. But if test papers be exposed to the vapour of the pus, raised if necessary by heat, all the reactions are exhibited perfectly. He gives the following case:—

A man received a severe bruise of the ankle. Gangrene of the skin and subcutaneous tissues followed. The pus had an indescribable fœtor, and gave off vapours which restored reddened litmus and blacked lead paper. So soon as the sores were bathed with this fetid pus, on the 10th day "he was seized with rigors, which having lasted an hour, were followed by fever, with extreme acceleration of the pulse, and abundant sweats. The febrile attacks were repeated until the 14th day, sometimes in the morning and sometimes in the evening. At a later period they were no longer preceded by a sensation of cold, and were merely characterised by fever and sweating. These fits were accompanied by a very fetid diarrhœa, the loss of strength became extreme, and the face of a paleness slightly tinged with yellow."

On the 16th day a large quantity of sulphide of ammonium was detected in the pus. On the 17th a small quantity of blood was taken, more fluid than usual, and of the colour of wine lees when slightly wetted. It gave off vapours of ammonia, as discovered by a glass rod dipped in hydrochloric acid; and of sulphuretted hydrogen likewise. The urine was clear, pale, with no sediment, and alkaline; its vapour gave the same reactions as that of the blood.

In another week, the fœtor of the pus abated, and the urine recovered its acidity.

Dr. T. Herbert Barker's experiments on the inhalation of cesspool vapours, and of sulphide of ammonium, give precisely similar results—excited circulation and thirst, twitching of the limbs, and dry dark tongue: after death the blood was found dark and ill coagulated; the corpuscles dissolved, and congestion of fluid blood in the vascular organs. (*On Influence of Sewer Emanations, Sanitary Review*, 1858. *Extract from Fothergillian Prize Essay.*)

Dr. Richardson, who obtained the Astley-Cooper prize for his essay on the Coagulation of the Blood, and whose zealous prosecution of experimental research is well known, has the following observations on this subject:—

"In cases where putrid matter is imbedded in the system, as when deep seated abscesses, open by fistulous canals to the air, exist in the organism, and contain pus in a state of partial decomposition, ammonia is fully generated by decomposition of the putrid material, and is sometimes, I have reason to suspect, when the exit for the purulent matter is not free, absorbed by the surrounding tissues,

and taken up into the blood. Here received, the toxical effect is not slow in being developed, and the 'typhoid' which succeeds is the result, not of so-called irritation, not of exhaustion from the drain, but of poison generated in the cavity and conveyed from it to the body at large." (*On the Coagulation of the Blood*, Lond. 1858, p. 353.)

The effect of a too alkaline state of the blood is shown in these cases by the corpuscles, which become crenate, many-sided, collapsed, or even dissolved.

To sum up our observations on the varieties of hectic fever: we have shown that there is one division of so-called hectic in which the symptoms depend upon intrinsic blood changes, which are caused by mal-assimilation, and which often accompany the beginning of tubercular and other deposits. Such feverish symptoms are very irregular, and may be so slight as to merge into mere cachexia.

But there is another set of cases of hectic, dependent upon absorption of decaying or putrid pus. Probably, if such pus finds its way bodily into the blood-vessels, we shall have pyæmia. If its vapour or serum, then, according to the quantity and intensity of the matter absorbed, we may have the acute hectic, the milder common hectic, or the putrid variety. (*See also ABSCESS*, p. 9.)]

[TREATMENT OF THE VARIETIES OF HECTIC. We cannot undertake to detail the treatment of that sort which accompanies broken health in general, otherwise we should be here repeating matters which will be found under the head of chronic inflammation and scrofula; or which would embrace the whole treatment of disorders of mal-assimilation.

But as regards the varieties of true hectic from absorption, the indications are palpably these two: first, to remove the local cause if possible, and whether or no to strengthen the system as much as possible.

The first indication will be fulfilled if there be a deep abscess in the breast or perineum, or elsewhere, by giving free vent to the matter. "If," says Hunter, "the hectic arises from local disease in such parts as the constitution can bear the removal of, then the diseased part should be removed by amputation." "I have known a hectic pulse at 120 sink to 90 in a few hours upon the removal of the hectic cause. I have known persons sleep sound the first night without an opiate, who had not slept tolerably for weeks before. I have known cold sweats stop immediately, as well as those called colliquative. I have known purging immediately stop upon the removal of the hectic cause, and the urine drop its sediment."

Every sort of local treatment capable of relieving the particular local condition present is to be put into force. But in a condition of poisoning by sulphide of ammonium, surgeons will do well to remove or neutralise the matter whose decomposition furnishes that substance. Abscesses, therefore, should be drained by M. Chassaignac's drain tubes, if they seem appropriate. Matter should not be allowed to bag or lodge, and adequate chemical means should be adopted to deodorise any that remains.

The writer lays stress on the word *adequate*. Vexatious is it to see a man rotting with a putrid abscess, and having perhaps a tray of charcoal by his bed-side and a little chloride of lime on a rag outside the wound. Surely there are chemical means

at hand, including watery solutions of creosote, of nitrate of lead, chloride of zinc, Condly's permanganates, and the chloride of lime; which, if effectually applied, will neutralise putrescent matter.

In the general treatment, the first point is to supply a most abundant and varied nutriment, so that the blood, filled with new and healthy matter, may better bear the exhaustion consequent upon the elimination of the old. The ingenuity of the practitioner will often be taxed to suggest fresh articles to stimulate an enfeebled stomach, for it is most true that novelty and change are most essential. First, we may mention the preparations of meat; essence of beef and gravy soups; turtle, mock-turtle, calves' tail, and other gelatinous soups; milk flavoured with rum, with orange peel, or vanilla; isinglass; fish soup, fish pudding with cream; custards thickened with pounded meat; potted beef or tongue; the starches in their turn, arrowroot, sago, tapioca, tous les mois and salep; Indian meal, chocolate and cocoa; the oily fishes, cod-liver oil, eels, American oysters; gum-arabic and tragacanth; lastly, the various wines and beers, especially Guinness's genuine Dublin porter.

Next to nourishment, the means of sharpening the appetite are to be cultivated. For most cases an acid tonic with quina in small doses, or some other light bitter, answers best; or perhaps the nitromuriatic or sulphuric acid.

For sleeplessness and pain, adequate doses of morphine should be given. When the paroxysms of shivering are diurnal and regular, the writer has sometimes succeeded in postponing or averting them by large doses of quinine, or by opiates, or ether, given before the fit, as in ague. But this plan does not answer many times in succession.

The perspirations may be mitigated by the dilute mineral acids, Griffiths' iron mixture, or, as Dr. R. Dickson suggests, by the oxyde of zinc.

Diarrhoea may be mitigated likewise by the mineral acids; or, if the tongue be red and aphthous, by bismuth, chalk, gum, and small doses of opium.

Vegetable bitters and astringents have their uses, provided they promote and do not interfere with the appetite and digestion. Pure tannin in grain doses; or still better, the decoction of oak-bark, or tincture of galls, is a very efficient and agreeable tonic; the pure bitter quassia or hop is also palatable; and the decoction of bark with nitric acid requires no praise. (R. Druitt.)

FINGERS, ABSCESSSES OF, see WHITLOW; AMPUTATION OF, see AMPUTATION; DISLOCATIONS OF, see DISLOCATION; FRACTURES OF, see FRACTURE.

[The fingers may be more or less numerous than ordinary, and when perfectly formed, require no surgical treatment. Of this abnormal development the former is of more frequent occurrence than the latter. The supernumerary digit is generally situated on the ulnar side of the hand: when on the radial side, which is much more rare, two thumbs are present. These irregularities are hereditary, and usually occur on both hands; they do not interfere with the usefulness of the hand or the remaining fingers. M. Nelaton mentions a case of four fingers only, or rather of three fingers and a thumb; the deficiency occurred on the left hand. Similar cases are on record affecting one or both hands. Imperfectly formed supernumerary fingers are occasionally found articulated

with the ulnar side of the metacarpal bone or first phalanx of the little finger, or with the radial side of the analogous bones of the thumb.]

FINGERS SUPERNUMERARY.

Since allowing the redundant number of fingers to remain would keep up deformity, and create future inconvenience, the surgeon is called upon to amputate them. The redundant fingers may be with, or without, a nail; seldom more numerous than one upon each hand; generally situated just on the outside of the little fingers; and, so far as my observation extends, incapable of motion in consequence of not being furnished, like the rest of the fingers, with muscles. For the most part, the phalanges are also imperfectly formed, or deficient. The best plan is to cut off supernumerary fingers with a scalpel, at the place where they are united to the other part of the hand. The operation should be performed while the patient is an infant, that is to say, before the superfluous parts have acquired much size.

FINGERS, PERMANENT CONTRACTION OF.

Baron Dupuytren has made some interesting observations on this affection, to which each of the fingers, but especially the ring-finger, is liable. Most of the individuals who have this infirmity have been accustomed to make efforts with the palm of the hand, and to handle bodies of great hardness. When a tendency to the complaint begins, some difficulty is experienced in extending the fingers; and the affected one, usually the ring-finger, soon becomes contracted; the metacarpal phalanx being first implicated, and the others afterwards inclining in the same direction. In this stage the flexion of the two adjacent fingers becomes more marked, but no knottiness is yet perceptible in front of, and around the cord on the palmar side of the ring-finger. Its second and third phalanges are straight and movable; the first is bent more or less to a right angle, and is movable on the metacarpal bone; but it cannot be put into the straight position by the most violent efforts. Dupuytren refers to a case in which a trial was made to cure the patient by means of the application of different weights, which were increased up to 150 lbs., without the flexion being removed.

When the ring-finger has become very much bent, the skin is thrown into curved folds, the concavities of which are towards the fingers, and the convexities towards the radio-carpal articulation. On first inspection one might suppose the skin to be diseased; but this is not the case. A tense cord is felt on the palmar side of the finger; it extends towards the first phalanx, and may be traced to the upper part of the palm. When the finger is bent, it disappears almost entirely. If attempts be made to extend the fingers, the tendon of the palmaris muscle is felt to move, and the motion is propagated to the upper part of the palmar fascia. The patient is unable to grasp largish bodies; and, if he try to take hold of them more forcibly, or an endeavour be made to extend the fingers, he experiences acute pain. The causes of this disease were formerly referred either to thickening and contraction of the skin, spasm of the muscles, disease of the flexor tendons, or that of their fibrous sheaths, or some change in the articular surfaces and lateral ligaments. All was un-

certainly, when Dupuytren had an opportunity of dissecting a hand in which this infirmity existed. A drawing having been first made of it, the integuments were removed from the palm and palmar aspect of the finger, after which the folds and wrinkles had entirely disappeared. From this it was clear that the disorder did not depend upon the state of the skin. As soon as the palmar fascia had been exposed, it was found to be tense, contracted, and shortened, and that from its inferior part cords or bands proceeded to the sides of the affected finger. On attempts being made to straighten the finger, M. Dupuytren observed that the fascia became tense. He then divided the prolongations of it extending to the sides of the finger. The contraction ceased immediately, and the fingers assumed a very slightly bent position. In fact the disease was ascertained to be owing to the extreme tension of the palmar fascia, brought on by a contusion of the palm, or the long continued pressure of hard substances upon it. The plan of cure adopted by M. Dupuytren consisted in making a transverse incision, about ten lines in length, over the metacarpo-phalangeal joint of the ring-finger. The skin was first divided, and then the palmar fascia. As soon as this had been done, the finger became straight, and could be extended almost as readily as in the natural state. After the operation the hand was fixed with a bandage upon a piece of pasteboard for a few weeks, and the fingers kept extended. In one case M. Dupuytren made semicircular incisions; one at the base of the ring-finger in order to divide the two digital and lateral-prolongations of the palmar fascia, sent to this finger; the other, an inch and a quarter from the first, in the palm of the hand, for the purpose of dividing the digital prolongation at its root, and thus detaching it from the palmar fascia. (See *Dupuytren Clin. Chir.* t. i. art. 1.)

In a lecture, delivered subsequently to the preceding observations, M. Dupuytren adverts to flexions of the fingers arising from other causes; as a previous wound of the palm, known by the scar; alteration in the formation of the phalanges, by disease, and unattended with the kind of cord observed when the palmar fascia is implicated; and a division of the extensor tendons with a cutting instrument, which, not being united again, leave the flexors without any antagonists. A contused wound, producing sloughing of the skin of the palm, may have the same result if its edges be suffered to be drawn together, instead of cicatrization being completed by the formation of a new cutaneous texture. (See *Clin. Chir.* t. i. p. 521.) Burns of the palm are frequently followed by this deformity when the preceding indication is neglected. Amongst other causes of permanent flexion, M. Dupuytren notices deformity of the articular surfaces of the phalanges, produced by the long continued position of the fingers in certain employments, as in lacemakers, tailors, &c.; by wounds of the flexor tendons, or their displacement, in consequence of having been extensively laid open for the cure of whitlow. The wound of a joint may be another cause of contraction of the finger; and a gunshot-injury of the flexor muscles may lead to the same consequence. M. Dupuytren's observations on this subject seem to me equally original and valuable. The toes are also liable to a contraction, dependent upon a state of the plantar fascia, corresponding to that of the palmar.

Dupuytren's view of the cause of contraction of the fingers above alluded to, viz. that the bands hindering the extension of the finger were produced by a permanent contraction of portions of the palmar fascia, was also held by the late Mr. Henry Cline, and, as would appear from an extract taken from his lectures, and published in one of the volumes of the *London Medical Gazette*, even prior to the period when Dupuytren taught the corresponding doctrine. The former had also anticipated the latter in the practice naturally dictated by such contemplation of the cause of the deformity. MM. Goyrand and Velpeau, however, object to the explanation of the subject given by Dupuytren, because the digital slips of the palmar fascia terminate in, and are fixed to the base and sides of the root of each finger, whilst the diseased band is situated in the middle of the finger, and is often prolonged to the third phalanx. They both concur, therefore, in ascribing this contraction to the transformation of a part of the subcutaneous cellular tissue in front of the phalanges into a fibrous band. M. Sanson also believes that this is the ordinary case, and that the contraction of the palmar fascia is an exception. The treatment recommended by M. Goyrand, is to make a longitudinal incision through the skin, over each band, when extended; to separate the lips of the wound; to detach the fibrous cords by dissection, and to cut across them when thus detached from their connections. (See *Gaz. Méd.* No. xxxi. and xxxii. Août, 1835.) Sir Astley Cooper passes a narrow knife under the cord, which is cut through without dividing the skin.

[The fingers are subject to a congenital deformity resembling the web-foot of aquatic birds or animals, in which the skin passes from one finger to another, connecting their lateral surfaces for a greater or less extent. These deformities vary greatly, both as to the width and length of the connecting web; sometimes it extends only to the first phalanx, at others it implicates the whole length of the fingers; in one instance the intervening web may be an inch wide or more: in another, the adhesion between the fingers may be close and intimate. In the most extreme cases, the fingers are enveloped in one cutaneous covering without intervals between the fingers, the phalanges of which may, however, be distinctly felt. Various modes of operative procedure have been devised for the removal of these deformities. No one plan is applicable to all the cases; the surgeon must in each individual instance select the operation most suitable to its peculiarities. The most simple plan is to divide the web longitudinally into two lateral halves from its free edge to the cleft between the fingers, then to adjust by means of sutures the edges of each lateral half, so as to facilitate their union by the first intention. Unfortunately the web is always narrow exactly at the cleft between the fingers, and when it is divided the edges of each lateral half become widely separated; the consequence is that they can only be brought in contact by force, and union is rarely effected. The granulating surfaces resulting after the failure of union on either side, cannot be prevented from coalescing, new skin will not form over them, and in spite of all modes of dressing the deformity in many cases will recur. To obviate this frequent cause of failure it has been proposed, in the first instance, to make a triangular flap from the posterior fold of the web; this flap is to be left at-

tached at its base, and is to correspond in shape and size to the space between the knuckles; its apex should be directed towards the free edge of the web; the flap being dissected back is to be applied to the cleft between the fingers, and must be cut of sufficient length for this purpose. The remainder of the web is now to be divided longitudinally into lateral halves; the edges of each lateral half are to be adjusted by sutures, and the triangular flap fitted into the cleft, and there maintained by the same means. It has also been suggested to make an anterior and posterior triangular flap from the web, to truncate their apices, and unite them by sutures between the fingers before making the longitudinal section of the web. A very ingenious operation is described by M. Nélaton, which must effectually prevent the growing together of the contiguous surfaces of the fingers. It consists in dividing the web into a posterior and an anterior flap; the posterior flap being intended to cover the raw surface of one finger, and the anterior that of the other. Each flap is formed by one longitudinal and two transverse incisions, each is the counterpart of the other, and has three raw unattached edges, and one attached. They are cut in the following manner. A longitudinal incision is made in the centre of the phalanx of one finger, on its dorsal aspect for the posterior flap, on the palmar aspect of the other for the anterior flap; the length of the incision must correspond with the depth of the web; from either extremity of the longitudinal incision, a smaller transverse one is to be made towards the phalanx of the connected finger. The lower transverse incision will correspond to the free edge of the web; the upper will cross the cleft between the fingers. Each flap is now to be dissected back towards the contiguous finger; in doing this the two folds of the web will be separated from each other, one entering into the formation of the posterior flap, the other into the formation of the anterior. Each flap will now be found to be attached by one edge only, and is to be wrapped round the denuded surface of the finger to which it is attached. The flaps are to be adjusted by strips of adhesive plaster and by sutures.]

FISSURE (from *findo*, to cleave asunder). A fine crack in a bone is so called.

FISTULA, an opening, the consequence of a wound, abscess, or ulceration; it has no disposition to heal, and is connected with a channel, or canal, running more or less deeply and extensively in the soft parts. From the resemblance of this channel to the tube of a pipe, or reed, the term is derived. A fistula commonly leads to the situation of some disease keeping up suppuration; and from which place the matter cannot readily escape. Thus, the presence of a dead piece of bone, or of a foreign body often keeps up suppuration, and the fistula continues for the discharge of the matter. When an abscess forms near the anus, the matter lodges, the part is disturbed by the action of the sphincter, and a *fistula in ano* is produced. Sometimes a fistula is produced by the continual discharge of some healthy secretion through a wound, or ulcer, as exemplified in salivary, lachrymal, and urinary fistulæ. The lining of old fistulæ may assume the appearance of certain mucous membranes, though follicles and villi, like those of the intestinal canal, have never been observed in it. As Andral remarks, when most perfectly organised, it can only

be compared to the most simple mucous membranes, such as those of the ureters, or lesser branches of the hepatic ducts. The lining of fistulæ, like mucous membranes in general, when not irritated, is pale and of a greyish colour; but, if affected with acute or chronic inflammation, it exhibits the same shades of injection and redness seen in a mucous texture. It is also liable to certain affections, which pertain almost exclusively to mucous membranes, as fungous growths, callosities, &c. The cellular tissue, connected with the lining of fistulæ, may become thickened and indurated, just like the submucous cellular tissue in general. Finally, just as adhesions never take place between the different points of a surface lined by a mucous membrane, unless a solution of continuity has taken place in it, so the sides of a fistula cannot adhere together, and its cavity be obliterated, unless incisions be made to bring the textures and the membrane-like investment of it into contact. (See *Andral, Précis d'Anat. Pathol.* t. i. p. 261.)

FISTULA IN ANO. See **ANUS**.

FISTULÆ IN PERINÆO. Incisions in the urethra generally heal with great facility; a fact amply proved by the common result of lithotomy: but, when apertures are formed in the urethra, either from diseased states of the constitution and the part together, or of the latter alone, and when they are accompanied with any considerable destruction of the sides of the urethra, and of the corpus spongiosum, they are difficult of cure. (*Sir B. Brodie, in Med. Gaz.* Dec. 26. 1835. No. 13.)

When the methods recommended for the removal of strictures (See **URETHRA, STRICTURES OF**) have not been attempted, or not succeeded, nature endeavours to relieve herself by making a new passage for the urine, which, although it often prevents immediate death, yet, if not remedied, is productive of much inconvenience and misery to the patient through life. The mode in which nature endeavours to procure relief is by ulceration on the inside of that part of the urethra which is enlarged, and situated between the stricture and the bladder. Thus the urine becomes applied to a new surface; irritating the part, and occasioning the formation of an abscess, to which the urine has access; and when the matter is discharged, be it by nature or by art, the urine passes through the aperture, and generally continues to do so, whilst the stricture remains. (*Sir A. Cooper, Surgical Essays*, part ii. p. 212.)

In rare cases a fistula in perinæo occurs as a consequence of severe gonorrhœa. The urine comes away in a very small stream, because the urethra is inflamed, swollen, and contracted. At last, a pain is felt in the perinæum, a tumor is felt there; and this state is frequently attended with complete retention of urine, or with great difficulty of making water. At length the tumor bursts, or is opened with a lancet, pus is discharged, then the difficulty of making water subsides, and, a day or two afterwards, the patient finds that, whenever he voids his urine, a portion of it comes through the opening in the perinæum. (*Sir B. Brodie, in London Med. Gaz.* vol. for 1835—36, p. 486.)

The ulceration, which is usually on the side of the urethra next the external surface, commonly begins near, or close to the stricture, although the stricture may be at a considerable distance from the bladder. The stricture is sometimes included

in the ulceration, by which means it is removed; but this does not frequently happen.

[If the urethra gives way rapidly, the urine readily gets into the loose cellular textures of the scrotum and penis, and it may diffuse itself throughout them, producing violent and destructive inflammation; a condition known as *EXTRAVASATION OF URINE*.] The presence of the urine prevents the adhesive inflammation from taking place; it becomes the cause of suppuration wherever it is diffused, and the irritation is often so great that it produces mortification, first in all the cellular tissue, and afterwards in several parts of the skin; all of which, if the patient live, slough away, making a free communication between the urethra and external surface, and producing what are termed *fistulae in perinæo*, though it is plain enough to every surgeon who knows the correct meaning of the word *fistula*, that a recent opening, produced in the perinæum by ulceration or sloughing, ought not to be called a fistula immediately it is formed, and, at least, not until it has acquired some of the characters specified in my explanation of the term *fistula*.

A fistula in perinæo, then, is the result of an abscess in the perinæum, communicating with the urethra at one extremity, and opening externally at the other. "The whole or part of the urine flows through the fistula, whenever the patient makes water; the constant irritation of the urine causes the sides of the fistula to become hard and callous; and, at last, a sort of button-like projection, with the orifice of the fistula in the centre, is discovered in the perinæum. The fistula differs in length and size, and the opening into the urethra differs in size also. There is sometimes a single fistula, sometimes there are several; and, accordingly as the fistula is larger or smaller, accordingly as there are more or less sinuses, communicating with the urethra, so does a larger or smaller quantity of urine escape through this unnatural passage whenever the patient makes water. Sometimes the urine thus voided amounts to only a few drops, sometimes it comes away in a small stream, and sometimes it comes away in so large a quantity, that that which is voided by the perinæum is greater than what is voided in the natural way." (*Sir B. Brodie, in Lond. Med. Gaz. vol. for 1835—36, p. 486.*) I have seen a few examples in which all the urine was discharged through the fistula. In the King's Bench there was a man, about four years ago, who had been passing the whole of his urine through a fistula in the perinæum for fourteen years; and the anterior portion of the urethra seemed to be obliterated.

Although a fistula in perinæo is productive of much distress, inasmuch as the flow of urine in this direction wets the patient's dress, irritates the integuments, and sometimes the urine causes a good deal of pain as it is running out, the fistula, as Sir Benjamin Brodie has well observed, is not an evil unmixed with good. If a man has a stricture, it saves him from the ill consequences of a retention of urine. A spasm affects the stricture and he cannot make water through the natural passage; but the fistula being formed, the urine escapes from it, and thus the return of retention of urine, and the ill consequences of over-distension of the bladder, are prevented.

When the disease is the consequence of gonorrhœa, there is generally only a single abscess; but,

when it is connected with a stricture, there may be many abscesses formed in succession. Thus, a patient, with a stricture of long standing, may have fistulae produced in various directions, and terminating in the perinæum, the middle of the scrotum, or even in the groin, the nates, or the rectum. When the matter and urine have been freely discharged through one opening, a fresh abscess is not often formed; but, in the opposite case, several abscesses are liable to follow. (*Ib.*)

In many cases the matter is putrid and offensive, in consequence of the pernicious effects of the urine, and the admixture of it and dead cellular tissue with the pus which is produced. Sir Benjamin Brodie is of opinion that the matter may even act as a poison on the system; and, on this principle, he partly explains the repeated shiverings during the formation of the abscess, the dry brown tongue, hot skin, frequent pulse, and other typhoid symptoms.

According to Mr. Hunter, when ulceration takes place further back than the portion of the urethra between the glans penis and membranous part of the canal, the abscess is generally more circumscribed.

A fistula in perinæo, and extravasation of urine, producing gangrene, are both connected with ulceration of the urethra; but, as Sir Benjamin Brodie remarks, the ulceration occurs under different circumstances. "If the patient be making water in a small stream, and a little ulcer forms behind the stricture, the greater part of the urine flows out by the natural passage, and it is not probable that more than a few drops will dribble into the cellular membrane, through the ulcerated orifice. But if the patient has complete retention of urine, if the stricture be so contracted that not a drop of water can pass through it, and, if then the urethra ulcerates behind the stricture—the next time the patient tries to make water, he strains with the bladder and abdominal muscles, the urine cannot pass by the natural passage, and it is driven by the muscles, as by a syringe, into the cellular membrane of the perinæum first, and into that of the scrotum, penis, and nates afterwards, and a great deal of urine is extravasated. In the one case, it *dribbles* into the cellular membrane; in the other, it is *driven* into it; and hence sloughing under certain circumstances, and an abscess under others." (*Sir B. Brodie, in London Med. Gaz. vol. for 1835—36, p. 487.*)

[It is quite certain that abscess sometimes occurs without any primary lesion of the urethral walls, and this being opened in the perinæum, gives exit to no urine at first. After a few days, however, a communication forms between the cavity of the abscess and the urethra, and a fistula results. This is analogous to what takes place in ischio-rectal abscess bordering on the rectum, and gives rise to *fistula in ano*.]

Extravasated urine sometimes insinuates itself into the corpus spongiosum urethræ, and is immediately diffused through the whole, even to the glans penis, so as to produce a mortification of all those parts. A fatal instance of this kind is reported by Sir C. Bell. (*Surgical Obs. vol. i. p. 96.*)

Although the ulceration of the urethra be in the perinæum, the urine generally passes easily forwards into the scrotum, which contains the loosest cellular tissue in the body; and there is always a hardness, extending along the perinæum

to the swelled scrotum, in the track of the pus. (*Hunter.*)

The direction which the extravasated urine takes is determined by the connection of the superficial with the deep perinæal fascia below the transverse muscle. This connection prevents the urine from extending towards the thigh or the buttock; and, if it become very widely extravasated it does not pass downwards or backwards, but forwards into the scrotum and penis, and then into the groins and cellular tissue of the parietes of the abdomen, and this nearly up to the ribs.

[When extravasation has taken place, free incisions should be made in the parts where swelling and tension are most evident, either in the perinæum, scrotum, or on the penis itself, in order to give abundant means of exit to the effused urine, and to the products of inflammation.]

Sir Astley Cooper is of opinion that, as soon as the abscesses, which are the forerunners of the fistula, can be plainly felt to contain a fluid, it is best to open them. They not unfrequently then heal up expeditiously without any fistulous orifice being left, and a tendency to those dangerous extravasations of urine is also prevented, which, if the abscesses are not opened early, often prove destructive to life. (*Surgical Essays*, part ii. p. 212.)

The occurrence of ulceration can only be prevented by overcoming the stricture; but when the urine is diffused in the cellular tissue, the removal of the stricture will generally be too late to prevent mischief, although it will be necessary for the complete cure. Therefore, an attempt may be made to pass a bougie, or rather a catheter, for perhaps the stricture may have been destroyed by the ulceration, so as to allow the instrument to be introduced. In these cases Sir A. Cooper expresses a preference to metallic bougies, the size of which is to be gradually increased, until their diameter exceeds the natural diameter of the passage. In some instances, however, he considers it advisable to introduce a metal catheter, of large size, and to allow it to remain in the bladder, so as at once to act upon the stricture, and hinder the urine from passing through the preternatural opening. In this manner a permanent cure may often be effected.

The experience of modern surgeons tends to prove, however, that particular cases form exceptions to the plan of employing bougies, or catheters, though a fistulous opening may have occurred; as when the apertures in the urethra are the consequences of ulceration and abscess, unaccompanied by stricture, and take place in a bad constitution, perhaps only preceded by a slight discharge from the urethra. Here bougies would increase the tendency to ulceration, and aggravate the local and constitutional irritation. (*Sir A. Cooper*, p. 216.) I believe that this is the right view of the latter point, because, when an abscess and fistulous opening form from gonorrhœa, they arise not so much from diminution of the canal of the urethra, but from the tendency in certain constitutions to have abscesses of this description produced by even slight degrees of irritation in the urethra. Hence, if a catheter be useful in such a case, it is not by dilating the urethra, but conducting the urine through it, without allowing it to enter the abscess. A bougie would serve no useful purpose.

[Furthermore, if, in a case of extravasation, free

incisions have been made, and the urine flows off freely by them, which will be the case if they have been properly made, there is no occasion to pay much attention to the stricture at first; on the contrary, it is better to wait for a few days before applying any systematic treatment to it. The stricture will be more amenable to dilatation after rest, and the removal of the urine through the artificial openings which have been made.]

In fistulæ in perinæo from stricture, the cure mainly depends upon the diagnosis of the primary disease,—the obstruction in the urethra. In nineteen cases out of twenty, by the time that the stricture is fully dilated, the fistula has healed. It is more easy (as Sir Benjamin Brodie observes) for the urine to pass along the natural passage, if it be of its proper diameter, than it is for it to pass through the oblique passage of the fistula. The fistula has generally a kind of valvular opening into the urethra, which the urine does not readily enter; and when the stricture in front of the fistula has been dilated, and the urine has a free passage in that direction, it ceases to flow in the other.

Frequently the new passages for the urine do not heal, on account of the stricture not being removed; and even when this has been cured, they often will not heal, but become truly fistulous, and produce flesh inflammation and suppurations, which often burst by distinct openings. Such new abscesses and openings often form, in consequence of the former ones having become too small, before the obstruction in the urethra is removed.

Such diseases are sometimes accompanied by intermittent febrile symptoms, which do not yield to bark; but cease as soon as the fistulæ and disease of the urethra have been cured.

Cases occur where, from the communication of the fistula with the urethra being unusually large, or from there being several fistulæ, or from some other cause, the cure of the fistula, or fistulæ, does not immediately follow the removal of the stricture. Under these circumstances Sir Benjamin Brodie recommends an examination of the perinæum to be made, in order to ascertain whether there is any cavity in it in which the urine or pus lodges. If the orifice of the fistula is such that matter formed at the bottom of it does not readily escape, either the orifice should be dilated, or a fresh opening made elsewhere, according to the rules commonly recognised for the treatment of abscesses in general. But, if there is no impediment of this kind to the cure, and the stricture has been duly dilated, Sir Benjamin Brodie approves of the introduction of an elastic gum catheter into the bladder, and of its being continued there for the evacuation of the urine, under which treatment a cure of the fistula will often take place.

In some instances, the latter plan should not be continued beyond a certain stage of the case: at first, the catheter kept in the urethra frequently promotes the healing of the fistulæ; but, in the end, it may have the contrary effect, by acting at the bottom of the wound, as an extraneous body. This state of the case is particularly adverted to by Sir Benjamin Brodie:—"In many cases (says he) the permanent retention of a gum catheter in the bladder does not answer the intended purpose with respect to the cure of the fistula. It would do so if it altogether prevented the urine from

flowing through it; but the fact is, that it does not in reality produce this effect; after three or four days a little urine always finds its way by the side of the gum catheter, and gets into the fistula, although the greater part is drawn off through the catheter. Another circumstance also takes place. The gum catheter acts like a seton, inducing inflammation and suppuration of the mucous membrane of the bladder; and some of the pus which is secreted passes through the fistula and keeps it open, as much as it would be kept open by the urine itself." (*Sir B. Brodie, Op. et vol. cit. p. 488.*)

If there be reason to suspect this to be the case, the best plan is to draw off the urine about every four hours and withdraw the catheter directly after each evacuation. The aim should be to let all the urine which is secreted be thus removed by the catheter, and no opportunity afforded for it to enter the fistula. But, as Sir Benjamin Brodie has explained, the urine sometimes cannot be comfortably retained the time required; and if the catheter be more frequently introduced it becomes a source of irritation, keeps up suppuration, and does as much harm as if it were continually retained. In a case which recently occurred, the permanent retention of catheters in the urethra, and the frequent introduction of them, were plans both tried unsuccessfully. One or two large deep cavities, filled with matter, and communicating with the fistulæ, were laid open, and this was followed by considerable improvement. But the use of catheters in any way always led to fresh abscesses, and could never be continued long and regularly enough without bringing on great local and constitutional disturbance. The constitution was indeed a truly irritable one. Abscesses at length formed successively in the testes, cord, and in the cellular tissue behind Poupart's ligament. An attack of diarrhœa came on, the appetite failed, and the gentleman died.

The opening of a fistula in the perinæum may sometimes be healed by touching it with the nitrate of silver, but the deeper part of it often continues unhealed, and abscesses form again. Hence, Sir Benjamin Brodie tried the plan of stimulating the bottom of the fistula, while he took measures to prevent the orifice from healing prematurely. A small quantity of nitrate of silver was melted in a platinum spoon, and the end of a probe, having been coated with it, was passed quite to the termination of the fistula, the orifice of which was then slightly touched with caustic potash. The method sometimes answered and sometimes failed.

If all these plans prove ineffectual, Sir Benjamin Brodie is in favour of trying what the daily introduction of a good-sized metallic instrument will accomplish.

When a perinæal fistula exists, communicating with the urethra, but having no external opening, a free incision is to be made into the abscess, and the rest of the treatment conducted on the principles applicable to common fistulæ in perinæo. Sometimes a small indurated lump, not bigger than a horse bean, may be felt in the perinæum. It may keep up for a long period a kind of gleet, in consequence of urine entering its cavity, and the matter oozing into the urethra. The cure consists in puncturing it, dilating the urethra with catheters, and, if necessary, touching the deeper part of the wound with caustic potash. (*Sir B. Brodie, Op. cit.*)

Some practitioners occasionally resort to the actual cautery for healing fistulæ in perinæo which resist milder plans.

The following method of laying open such fistulæ was more commonly followed a few years ago than at the present day.

As little as possible of the sound part of the urethra must be opened. Hence, the surgeon is guided to the inner orifice of the fistulæ by means of a staff, introduced (if possible) into the bladder, and a probe passed into one of the fistulous passages. The probe should be first bent, that it may more readily follow the turns of the fistula. When it can be made to meet the staff, so much the better, for then the operator can just cut only what is necessary. When the fistula is so straight as to admit of a director being introduced, this instrument is the best. When neither the probe nor the director can be made to pass into the staff, the sinuses are to be opened as far as the first instrument goes, and then the continuation of the passage sought and laid open. The difficulties of this dissection, however, through the thickened diseased state of the parts in the scrotum and perinæum when no staff can be passed, are only to be duly appreciated by a man who has either made the attempt himself, or seen it made by others. I have seen one of the first anatomists in London fail in two instances to trace the continuation of the urethra, and baffled in the endeavour to pass an instrument. The difficulty and confusion arising from the hardened enlarged state of the parts which are cut, have been well depicted by Sir C. Bell. (*Surgical Obs. vol. i. p. 129.*)

When fistulæ in perinæo have been laid open, the wounds are to be at first dressed down to the bottom, which will prevent a premature reunion of the parts near the surface, and make the granulations shoot from the bottom, so as to consolidate the whole by one bond of union. (*Hunter, On the Venereal Disease, 2nd ed.; See also Urinary Abscesses and Fistulæ.*)

[When from sloughing after extravasation, or from other causes, a large opening exists in the perinæum, or, as most commonly happens, just in front of the scrotum, and a portion of the urethra itself has been destroyed, some plastic procedure is necessary in order to restore and close in the canal. For an account of the various operations available in these circumstances, see URETHROPLASTY.]

FISTULA, SALIVARY. See PAROTID DUCT.

FLUCTUATION. The perceptible motion communicated to any collection of purulent matter, or other kind of fluid, by applying the hands to the surface of a tumor, and pressing with them alternately, in such a manner, that the fingers of one hand are employed in pressing, or rather in briskly tapping upon the part, while those of the other hand remain lightly placed on the opposite side of the swelling. When the ends of one set of fingers are thus delicately applied, and the surgeon taps, or makes repeated pressure with the fingers of the other hand, the impulse given to the fluid is immediately perceptible to him, and the sensation thus received is one of the principal symptoms by which practitioners are enabled to discover the presence of fluid in a great variety of cases. Great skill in ascertaining by the touch the pre-

sence of fluid in parts, or being endued with the *tactus eruditus*, as it is termed, distinguishes the man of experience as remarkably, perhaps, as any quality that can be specified.

When the collection of fluid is very deeply situated, the fluctuation is frequently obscure, and sometimes not at all distinguishable. In this circumstance the presence of the fluid is to be ascertained by the consideration of other symptoms. For example, in cases of hydrops pectoris and empyema, surgeons do not expect to feel the undulation of the fluid in the thorax with their fingers; they consider the patient's difficulty of breathing, the uneasiness attending his lying upon one particular side, the œdema of the parietes of the chest, the dropsical affection of other parts, the more raised and arched position of the ribs on the affected side, the preceding rigors, fever, and several other circumstances, capable of being learned with the aid of the stethoscope, from which a judgment is formed, both with regard to the presence and the peculiar nature of the fluid.

FOMENTATION. The application of flannel or cloths wet with warm water, or some medicinal decoction. Fomentations are chiefly of use in relieving pain and inflammation, and in promoting suppuration, when this is desirable. Some particular decoctions, however, are used for fomentations, with the view of affecting, by means of their medicinal qualities, scrofulous and other sores of a specific nature. I shall merely subjoin a few of the most useful fomentations in common use.

FOMENTUM AMMONIÆ HYDRO-CHLORATIS. ℞. Fomenti communis ℥ ij. Ammon. Hydroch. ʒ j. Spirit. camph. ʒ ij. Just before using the hot decoction, add to it the hydrochlorate of ammonia and spirit.

FOMENTUM CHAMÆMELI. ℞. Lini contusi ʒ j. Chamæmeli ʒ ij. Aq. distillat. ℥ vj. Paulisper coque, et cola. A fomentation in very common use.

FOMENTUM CONII. ℞. Fol. conii recent. ℥ j. vel. Fol. conii exsiccata. ʒ iij. Aq. comm. ℥ iij. Coque usque reman. ℥ j. et cola. Sometimes applied to scrofulous, cancerous, and phagedenic ulcers.

FOMENTUM GALLÆ. ℞. Gallæ contusæ, ʒ ss. Aq. ferventis ℥ ij. Macera per horam et cola. Used in prolapsus ani, and sometimes employed as a cold application in hæmorrhoids.

FOMENTUM PAPAVERIS ALBI. ℞. Papav. Alb. exsiccata, ʒ iv. Aq. pur. ℥ vj. Bruise the poppies, put them in the water, and boil the liquor, till only two quarts remain, which are to be strained. Employed for the relief of pain, whether from inflammation, neuralgic affections, ulcers, &c.

FORCEPS, an instrument much employed in surgery for a variety of purposes, and having accordingly various constructions. The general design, however, of surgical forceps is to take hold of substances which cannot be conveniently grasped or reached with the fingers; and, of course, the instrument is always formed on the principle of a pair of pincers, having two blades, either with or without handles, according to circumstances. The smallest forceps is that which is employed in the operation of extracting cataract, and which is useful for removing any particles of opaque matter from the pupil, after the chief part of the crystalline lens has been taken away.

Another forceps, of larger size, is that used for taking up the mouths of the arteries, when these vessels require a ligature, in cases of hæmorrhage. This instrument is also frequently employed for taking dressings off sores, removing pieces of dead bone, foreign bodies from wounds, and particularly for raising the fibres which are about to be cut, in all operations where careful dissection is required. This forceps resembles that which is contained in every case of dissecting instruments, and is often called the *artery* or *dissecting* forceps, from its more important uses.

Neither of the foregoing forceps is made with handles; each opens by its own elasticity; and the ends of the blades only come into contact when pressed together by the surgeon.

The following kinds of forceps are constructed with handles, by means of which they are both opened and shut:—

1. The common dressing forceps, contained in every pocket-case of surgical instruments, and used for removing dressings from sores, extracting dead pieces of bone, foreign bodies, &c.

2. Larger forceps, employed for extracting polypi from the nostrils, or foreign bodies from the pharynx.

3. Forceps of different sizes and constructions, used in the operation of lithotomy, for taking the stone out of the bladder, or for breaking the calculus, when it is too large to be extracted in an entire state.

4. Cutting forceps, as the common bone-nippers, with transverse edges, and the sharp forceps, made with the edges in the same line with the handles, used by Mr. Liston, and others, for the division of bones.

FRACTURE. A solution of continuity of one or more bones, produced in general by external force; but occasionally, by the powerful action of muscles, as is often exemplified in the broken patella.

Fractures constitute so interesting a branch of surgery, and the accidents themselves are so frequent and important, that the more scientific and successful views now entertained of the whole subject, than those prevalent forty or fifty years ago, must be highly gratifying to every admirer of the incessant progress of surgery towards perfection. Nor is this branch of surgery simply mechanical, or restricted to the consideration of bandages, splints, and other apparatus; but comprises questions and investigations not surpassed, in respect to their scientific character, by any others in the whole range of surgery.

Let it not be any longer supposed, therefore, that the treatment of fractures is only a mechanical business. In fact, whoever pretends to be capable of conducting it efficiently, without a due acquaintance with anatomy and pathology, and the principles on which inflammation, abscesses, gangrene, wounds, ulcers, erysipelas, hæmorrhage, and various febrile disturbances of the constitution should be treated, must absolutely be a simpleton, or an impostor; for all these complications frequently accompany or follow fractures. Under such circumstances, what man of common sense would trust his limb and life to a mere bone-setter? But the sequel of this article will enable the reader to judge of the truth of these observations.

1. DIFFERENCES OF FRACTURES.

The differences of fractures depend upon what bone is broken; what portion of it is fractured; the direction of the fracture; the respective position of the fragments; and, lastly, upon circumstances accompanying the injury, and making it simple, compound, or variously complicated.

1. *In respect to the bone affected.* Sometimes it is one of the broad bones, as the scapula, the sternum, or the os ilium. Sometimes it is a short bone, like the os calcis; but far more commonly it is one of the long bones. The situation and functions of the broad bones render their fractures unfrequent. The bones of the skull are the only exception to this remark; but here the assistance of the surgeon is required less for the solution of continuity itself, than for the affection of the brain, and the extravasation of blood, with which the case is apt to be combined. Fractures of the short bones are still more unusual, because these bones, being nearly equal in their three dimensions, are capable of greater resistance, and are not much within the reach of external violence. Besides, most of them are but little exposed to the operation of outward force, by their situation, or functions. Hence, except when limbs are crushed, fractures of short bones are generally caused by muscular action, which frequently breaks the patella, and sometimes the olecranon, and os calcis. The long bones, which serve as pillars, or arches of support, or levers, are, from the very nature of their functions, particularly liable to fractures.

2. *In respect to the part of the bone broken.* The long bones may be fractured at different points. Very often their middle portion is broken, and, in this circumstance, they usually break like a stick, which has been bent beyond its extensibility by a force applied at each end of it. Sometimes the fracture occurs more or less near the extremities of the bone, which is always an unfavourable event. Lastly, the bone is sometimes broken in several places, and the injury may be produced by two different causes, which operate successively, or simultaneously, upon the broken parts of the bone; or it may be occasioned by one single cause, which acts at the same moment upon several points of it. These distinctions of fractures, deduced from their particular situation (says Boyer), are not mere scholastic refinements; they have a truly important influence over the prognosis and treatment.

3. *In respect to the direction in which the bone is broken.* Thus, fractures are distinguished into *transverse* and *oblique*. The obliquity renders the surface of the injury larger, and materially increases the difficulty of maintaining the ends of the bone in contact, after the fracture has been set. Oblique fractures are subject to considerable variety, which depends upon the degree of their obliquity, and whether they are partly oblique and partly transverse. When a bone is broken in different places at once, and divided into several fragments, or splinters, the fracture is termed *comminuted*.

Duverney admitted another class of fractures, viz. *longitudinal*. (See *Maladies des Os*, t. i. p. 167.) Such cases were regarded by J. L. Petit as only imaginary, because he conceived that any blow, capable of breaking a bone longitudinally,

would more readily cause a transverse fracture. For the same reason, Louis absolutely rejected the possibility of longitudinal fractures.

The following case, however, is related by Leveillé. An Austrian soldier was put under his care in the year 1800, in consequence of being struck by a ball in the lower third of the leg at the battle of Marengo. He had walked to Pavia, a distance of several miles, after receiving the injury. In the end, amputation became necessary, and Leveillé preserved the tibia, upon which the impression of the ball was distinguishable. From this point proceeded several longitudinal and oblique lines, which extended from the lower third, towards the upper end of the tibia, and passed through the whole thickness of the parietes of the medullary canal. They were acknowledged to be really longitudinal fractures, by Dubois, Chaurrier, Duméril, Deschamps, and Roux. (*Nouvelle Doctrine Chir.* t. ii. p. 158.)

In several cases of fractured thigh-bones from gunshot violence, which were under the care of Dr. Cole and myself in Holland, the bone was split longitudinally to the extent of seven or eight inches. The fact, however, that bullets and other balls do produce longitudinal fractures, is now universally admitted. Boyer, who formerly denied the possibility of longitudinal fractures, was latterly of a different opinion:—“*On trouve néanmoins, à la suite des plaies d'armes à feu, les os fendus suivant leur longueur, jusques dans leurs articulations*,”—but he is correct when he adds, that such instances afford no proof of the possibility of a simple longitudinal fracture. (See *Maladies Chir.* t. iii. p. 10.) M. J. Cloquet has recorded a case, in which the fall of a building buried a man in the ruins, and occasioned several longitudinal fractures. (See *Pathol. Chir.* 4to. Paris.)

[Some other instances of *purely* longitudinal fractures, or fissures, are referred to by M. Malgaigne. They appear to be commonly associated with such serious injury to the limb as either to necessitate its removal or to cause the death of the patient. (See *Traité des Fract. &c.* t. i. p. 36.) Such a fracture is attended with little or no displacement, and is therefore scarcely recognisable during life, unless it happen to be accompanied by a wound which exposes it to view. Longitudinal fractures, however, combined with transverse or oblique fractures, are by no means uncommon; thus, for instance, it often happens that the femur or the humerus is broken across in its lower third, and the inferior fragment is split longitudinally into the knee or elbow joint.]

4. *In regard to the respective position of the fragments.* These differences are highly important, because the treatment essentially consists in obviating, or preventing, the displacement of the fragments. It is not to be supposed, however, that such displacement is a constant effect of all fractures, for it seldom takes place where there are two bones, and only one of them is broken. Neither does it invariably happen in every fracture of the neck of a bone, as is exemplified in certain fractures of the neck of the thigh-bone, the fragments of which sometimes change their relative situation only when the limb is too freely moved about. Fractures of the leg are also observed, in which there is neither a displacement of the fragments, nor an alteration in the shape of the limb, espe-

cially when the tibia alone is fractured near its upper part, where it is very thick. When the ulna alone is broken at its upper part, there is hardly ever any displacement. The corresponding surfaces of the fragments having a large extent cannot be separated, or can only be so with difficulty. Fractures of the fibula are also frequently unattended with displacement. But when both bones of the leg or fore-arm are fractured together, there is generally more or less displacement; and such is also the case when a fracture occurs in the thigh, or upper arm, where there is only one bone. Here the little extent of the surfaces of the fracture, and the great number of muscles, facilitate displacement.

The displacement may happen in respect to the diameter, length, direction, or circumference of the bone.

In respect to the diameter. In transverse fractures, this kind of displacement is frequently exemplified. The two fragments may either be in contact at a part of their surfaces, or they may not be in contact at all. In the latter circumstance, the limb is shortened by the ends of the fracture slipping over each other.

In respect to length. The mode of displacement, in which the ends of the broken bone pass more or less over each other, is chiefly noticed in oblique fractures, but sometimes in transverse ones, when the displacement, in the direction of the diameter of the bone, has been such that the surfaces of the fracture are no longer in contact. When the limb is shortened, it is generally by displacement of the lower fragment.

To the species of displacement here spoken of, may be referred that which takes place in fractures of the patella, olecranon, and os calcis; but with this difference, that the fragments, instead of passing over each other, recede from each other in the direction of the length of the bone, and continue separated by a more or less considerable interspace.

In respect to the axis of the bone. In this kind of displacement, the two fragments where they meet form an angle, and the bone appears bent. This displacement is often termed the *angular deformity*. It may occur in the leg, when the limb does not lie upon a surface exactly horizontal, and the heel is lower than the rest of the limb. The angular projection is then anterior. On the contrary, it would be posterior if the heel were too much raised. In fracture of the shaft of the thigh, it will happen if the lower part of the limb be too much depressed, or elevated, or placed too much outwards or inwards.

In respect to the circumference of the bone. This displacement occurs when the lower fragment performs a rotatory movement, while the upper one continues motionless. Thus, in fractures of the neck of the femur, if the foot is badly supported by the apparatus, its weight, together with that of the limb, and the action of the muscles, inclines it outward, and turns the lower fragment in the same direction. This is called the *rotatory displacement*.

Besides these displacements, there are others of a more complicated nature, which happen in several directions at once. For example, such is the displacement observed in a fracture of the thigh-bone, when the lower fragment is drawn upward and inward, while the foot is turned outward.

With respect to the causes of displacement, I may remark, that as the bones are only passive instruments of locomotion, they possess not, in their own organisation, any power capable of causing the change of situation which takes place; but yield to the impulse of external bodies, the weight of the limb or part, and the action of muscles.

The displacement may be produced by an external force, either at the moment when the fracture happens, and by the action of the same cause as that which breaks the bone: or it may be caused by the weight of the body, when the fracture precedes the fall: or, lastly, it may be brought on by some other external force, acting on the fragments, sooner or later after the occurrence of the injury.

The outward violence operates sometimes directly on the situation of the fracture; sometimes on parts more or less distant from it. In both cases, the action of the force is not confined to the production of the fracture, but is partly spent in causing a displacement of the fragments.

Fractures are generally occasioned by falls. Sometimes, however, the fall does not happen till after the leg, or thigh, is actually broken. The weight of the body then produces the displacement, by pushing the upper fragment against the soft parts, which are more or less lacerated. This is what happened to Ambrose Paré, who, being kicked by a horse, endeavoured to get out of the way, but instantly fell down, and the two bones of his left leg, which had been fractured, being impelled by the weight of the body, not only passed through the skin, but even through his stocking and boot. Boyer saw a nearly similar case, in a young man who was struck on the middle of the thigh by the pole of a carriage, which fractured the femur. The patient fell down, and in the fall the upper fragment was not only driven through the muscles and integuments, but also through his breeches.

The weight of the limb itself may produce displacement according to the direction, or circumference of the bone, as already detailed.

But of all the causes of the displacement of fractures, the action of the muscles is the most common and most powerful. Amongst the muscles surrounding a fractured bone, some are attached to it throughout its whole length, and are equally connected with both the fragments. Some arise from the bone above, and are inserted either into that, which is articulated with the lower fragment, or into the lower fragment itself. Lastly, others come from a point more or less distant, and terminate in the upper fragment. The muscles around the thigh-bone furnish examples of these three arrangements. The adductor magnus is attached to the bone through the greater part of its length. The long portion of the biceps, the semi-membranosus, and semi-tendinosus, come from the pelvis, and are inserted into the leg, a part with which the lower fragment is articulated, and all the motions of which it follows. The tendon of the adductor magnus is inserted into this fragment itself. Lastly, the iliacus, psoas, pectineus, &c. come from the loins and pelvis, and are attached to the femur, not far from its upper end.

The muscles attached to both fragments perhaps contribute but little to the displacement. They may, however, draw them to the side on which they are situated, and thus change the direction of the limb.

The displacement is principally owing to such muscles as are affixed to the lower fragment, or part with which this fragment is articulated. Suppose the humerus to be broken between its upper end and the insertion of the great pectoral. This muscle, aided by the latissimus dorsi and teres major, will draw the lower fragment inward, and displace it by drawing it to the inner side of the upper fragment, which remains motionless. In fractures of the neck of the thigh-bone, the upper fragment, included within the capsular ligament, affords attachment to no muscle; but all those which are affixed to the lower fragment tend to draw it upward and backward. In all cases, the lower fragment follows every movement made by the part of the limb with which it is articulated, and, consequently, the muscles attached to the bones of this last part of the limb become a powerful cause of displacement. Thus, in a fracture of the thigh-bone, the biceps, semi-tendinosus, and semi-membranosus, draw the leg, and with it the lower fragment, upward, inward, and backward, so as to make the lower end of the fracture ascend at the inside of, and rather behind, the upper one, the extremity of which then projects forward and outward. In a fracture of the leg, the gastrocnemius, soleus, and peronei muscles, acting upon the foot, draw the lower fragments of the tibia and fibula to the outer and posterior side of the upper fragments. For here, as well as everywhere else, the strongest muscles, in producing the displacement, draw towards their own side the end of the fracture on which they operate. And as the posterior muscles of the leg are far more numerous and powerful than the anterior, while those on its outside are not antagonised by any others, the displacement must happen in the direction backward and outward. Whenever, therefore, a bone is fractured at a given point, the knowledge of the muscles will enable a surgeon to determine *a priori* in what direction the displacement is disposed to happen.

Lastly, the muscles attached only to the upper fragment may contribute to the displacement. In a fracture of the thigh, situated immediately below the lesser trochanter, the psoas and iliacus muscles carry forward the extremity of the upper fragment, which elevates the integuments, and forms a more or less considerable projection near the fold of the groin. But the displacement of the upper fragment is generally less considerable and important than that of the lower.

The manner in which the displacement of fractures is effected by the action of muscles explains one circumstance which frequently attends these cases, especially fractures of the thigh, clavicle, and leg. This is a rising, a projection, of the upper fragment, or that which is nearest the trunk. One might believe, at first sight, that such projection is formed by the upper fragment quitting its natural situation, and rising over the lower one. But, on the least reflection, it becomes manifest that the upper end of the fracture projects only because the lower one is displaced, and drawn towards that side on which the strongest muscles are situated. Thus, in practice, in order to make the *rising end of the bone* (as it was termed) disappear, it is only necessary to reduce the lower fragment. If, instead of doing this, pressure be made on the projecting part, the design fails; and if the plan be still more forcibly pursued and con-

tinued, inflammation, ulceration, and sloughing, and the conversion of the case into a compound fracture, are likely to be the consequences.

5. *In respect to circumstances with which fractures are accompanied.* The most important division of fractures is into *simple* and *compound*. By *simple fracture*, surgeons mean a suddenly formed breach in the continuity of one, or more bones, without any external wound, communicating internally with the fracture. By a *compound fracture* they signify the same sort of injury of a bone, or bones, attended by a wound of the soft parts leading down to the fracture, which wound may be produced by the protrusion of one or both ends of the fracture through the skin, or by a ball, or other body, which enters, or otherwise wounds, the soft parts, at the same moment that it breaks the bone.

Fractures are said to be *complicated* when attended with diseases, or accidents, which render the indications in the treatment more numerous, and require the employment of different remedies, or the practice of sundry operations, for the accomplishment of the cure.

Thus, fractures may be *complicated* with severe degrees of contusion, wounds of the soft parts, injury of blood-vessels, a dislocation, or diseases and particular states of the constitution, as the scurvy, rickets, syphilis, cancer, pregnancy, &c.

The complication of fracture with dislocation is frequent in the ankle and vertebral column. In the first case, the dislocation usually precedes the fracture; but, in the second, the fracture of the body or bodies of the vertebrae, precedes the dislocation, which otherwise is exceedingly rare.

Under the head of differences in fractures may be fitly introduced that injury to the bones of children, which is denominated a *bending* of them from falls, blows, and external violence, since this injury requires the same treatment as fractures, although crepitus and separation of the fragments do not attend it. In 1821, Dr. J. R. Barton, of Philadelphia, published a valuable paper on the subject, including also remarks on another injury to the bones of children, which he calls a *partial* or *incomplete fracture* of a single bone, or both bones. These cases had been previously noticed by Underwood and Boyer, and perhaps by them alone. Dr. Barton has illustrated his paper by very accurate drawings of the deformity resulting from both of these accidents. (See *Amer. Med. Recorder* for 1821 and *Reese's Amer. ed. of this Dictionary*.) In the course of three years, Mr. Hart, of Dublin, met with five cases of partial fracture of long bones: one of the humerus; two of the radius; and two of the femur. "The diagnostic symptoms of this affection (he observes) are pain and a bent state of the bone injured, without absolute shortening of the limb. On the contrary, it is lengthened on the side to which the ends of the fractured bone project." (See *Dublin Journ. of Med. Science*, vol. i. art. i. 8vo. 1832.)

[A bending or partial fracture of the bones of children is now well known to be of not uncommon occurrence. It happens more frequently in the forearm than in any other part of the body, but it has been also observed in the humerus, femur, tibia, fibula, and clavicle. The fracture, of course, occupies the side of the bone which corresponds to the convexity of the bend, and extends to a variable distance through its substance. In

the attempts made to straighten the bone, a complete fracture is sometimes produced. It is very doubtful whether a *bending* of bones, unaccompanied by fracture of some portion of their thickness, ever takes place.

Under the head of differences of fractures should also be noticed, the separation which occurs in children and young persons at the line of union of the epiphyses with the shafts of the long bones. These epiphysary disjunctions are not unfrequent in the humerus, and in the radius at its lower extremity, but they may occur also in other situations. They do not differ in their mode of production, in their symptoms, or in the treatment required, from ordinary fractures in corresponding situations, and they admit of union with at least equal facility, and without interfering in any way with the subsequent growth and development of the bone. The only point of difference worth mentioning is the indistinct character of the crepitus which is elicited, in consequence of the smoothness of the separated surfaces. Further notice will be taken of these cases in speaking of particular fractures.]

2. THE CAUSES OF FRACTURES

Are divided into *predisposing* and *remote*.

In the first class are comprehended the situations and functions of the bones, the age of the patients, and their diseases. Superficial bones are more easily fractured than those which are covered by a considerable quantity of soft parts. The functions of some bones render them more liable to be fractured than others; thus the radius, which supports the hand, is more liable to be fractured than the ulna. The clavicle, which serves to keep the shoulder in its proper position, and to support on its arched extremity all the motions of the upper limb, is particularly subject to be broken. The gradual increase of the quantity of the phosphate of lime, in the structure of the bones, makes them brittle, in proportion as we advance in years; and, in old age, the proportion of the inorganised to the organised part is so great, that the bones are fractured by the slightest causes. In childhood, the animal and organised part bears a greater proportion to the earth, and the bones being, consequently, more elastic and flexible, are not so easily broken as in old age.

Lues venerea, cancer, rickets, scurvy, and scrofula predispose to fractures. B. Bell mentions two venereal patients, of whom the hardest and largest bones were completely broken by the ordinary action of the muscles of the limb. Sir Benjamin Brodie had a patient, whose clavicle broke exactly in the situation of a venereal node. (See *Med. Gaz.*) In the museum of University College, London, are two thigh-bones, taken from a patient who was using mercury for the cure of syphilis: one has several nodes upon it; the other broke as he was turning himself in bed. Fabricius Hildanus quotes from Sarazin, a physician of Lyons, the case of a gouty patient, sixty years of age, who, in putting on his glove, broke his arm above the elbow. Desault used often to speak of a nun of Salpetrière, whose arm was broken as a person was handing her out of a carriage. Louis, who was vexed that no union took place, was not a little surprised to find her thigh-bone experience the same fate one day as she was changing her posture in bed. It was then learned that she had a cancer

in her right breast. Leveillé observed similar cases in the Hôtel-Dieu; Sir Astley Cooper has met with others; and at this present time (March 1837), there is in University College Hospital a woman with cancer of the breast, whose humerus was broken about a fortnight ago by the ordinary action of the muscles. A few months ago she was in the same institution for a similar occurrence, and she had previously sustained the same kind of injury of other bones. A few years ago I attended a gentleman's coachman, who had a cancerous disease of the bladder, and whose thigh-bone broke at its upper third as he was turning himself in bed. Around the fractured part a scirrhus mass had been deposited between the periosteum and the bone; and one of the ribs was found in a similar condition, and also broken. The preparations are placed in the museum of University College. (See *Med. Chir. Trans.* vol. xvii.)

[In some of these cases, which have been now frequently noticed, the bones are found infiltrated with cancerous matter, which is first deposited so as to take the place of the natural medullary tissue, and afterwards causes a gradual absorption of the walls of the bone itself. Mr. Paget remarks that bones thus cancerous become liable to be broken with very slight forces; and to these conditions a certain number of the so-called spontaneous fractures in cancerous patients may be assigned. But he also thinks that others are independent of the specific deposition, and are due to the wasting and degenerative atrophy which the bones undergo, during the progress of cancer, even more than in other emaciating and cachectic diseases. (See *Lectures on Surg. Pathology*, vol. ii. p. 316.)]

According to Leveillé, the history of two girls is related by Buchner, one of whom died rickety at the age of sixteen, having broken the femur a short time before her death; and the other, after taking the breast very well for two years, and thriving for a time, became affected with rachitis, and met with the same accident as she was merely running along the street. (*Nouvelle Doctrine Chir.* t. ii. p. 163.)

Many extraordinary instances of fractures from the morbid softness and fragility of the bones are upon record. Suffice it here to refer to the *Philosophical Transactions*; *Mém. de l'Acad. Royale des Sciences*; *Act. Hafniens.*; *Ephem. Nat. Cur.* dec. I. ann. 3. obs. 112; Gooch's *Chirurgical Works*, vol. ii.; Saviard, *Obs. Chir.* p. 274; Gibson's *Institutes of Surgery*, vol. i. p. 370, &c. (See *Fragilitas* and *Mollities Ossium*.)

On the subject of fractures produced by scurvy, Marcellus Donatus; Saviard; Heyne de *Morbis Ossium*; Poupert's *Works* inserted in the *Mém. de l'Acad. des Sciences*, 1699; and the *Treatise* published at Verona, in 1761, by Jean de Bona, may be consulted. To these works I would add Lord Anson's *Voyage*, in which the effect of the scurvy in producing the absorption of the callus of old fractures, a disjunction of the fragments, and a renewal of ulcers which had been many years healed, is curiously exemplified.

Paré, Platner, Callisen, and several other writers, set down cold as a predisposing cause of fractures. This doctrine has originated from these injuries being more frequent in the winter time, but is erroneous, since, in cold countries, the greater number of falls which happen in winter from the slippery and very hard state of the roads, is a

circumstance that fully explains why fractures are then more common than in summer.

The remote cause of fractures is external force variously applied, in falls, blows, &c. In particular instances, the bones are broken by the violent action of the muscles attached to them; this is almost always the case with the fractured patella. Occasionally the olecranon and os calcis have likewise been broken by the violent contraction of the muscles inserted into them. With respect to the heel, Petit records two instances, one of which was communicated to him by Poncelet, and the other seen by himself in Madame La Présidente de Boissire, who met with the accident in walking at a gentle pace in the court of the Hôtel de Soubise. When the injury happens in leaping, or in falls from a high situation, Leveillé thinks it more probable that a portion of the os calcis is torn off by the powerful action of the muscles of the calf, than that it is broken by any blow immediately on the part. He states that Desault used frequently to cite two examples of this kind, one of which is recorded in his *Œuvres Chirurgicales*.

Whether the long bones can be fractured by the mere action of the muscles, has been a disputed point. In the *Philosophical Transactions*, a fracture of the humerus is ascribed to this cause; and Botentuit knew of the same accident being produced as a person was striking a shuttlecock with a battledore. According to Debeaumarchef, as a man was descending a ladder at a quick rate, his heel got entangled in an opening, and he made a violent exertion to avoid falling. The consequence was a fracture of the lower third of the leg. Curret informs us that a cabin-boy, aged seventeen, made a considerable effort to keep himself from being thrown down by the rolling of the ship. The femur was fractured by the powerful action of the muscles of the thigh. The lad had no fall, and, with some difficulty, supported himself on the other limb till he received assistance.

We are told, says Leveillé, by Poupée Desportes, that a negro, about twelve or thirteen years old, was seized with such violent spasmodic contractions of the muscles of the lower extremities that the feet were turned backward, and the neck of each thigh-bone was fractured, the ends of the broken bones also protruding through the skin upon the outside of the thigh. A cure was effected after an exfoliation. We read also, in the *Miscellanea Curiosa Acad. Naturæ Curiosorum*, that during a fit of epilepsy, a child, ten years old, had its left humerus and tibia broken, and that, upon opening the body, other solutions of continuity were observed. Chamseru assisted in dressing a child, eleven or twelve years old, that had broken the humerus in throwing a stone a considerable distance. (*Nouvelle Doctrine Chir.* t. ii. p. 164. 166.)

It is the belief of Richerand, however, that a long bone, when healthy, can never be broken by the mere contraction of the muscles. (*Nosogr. Chir.* t. iii. p. 12. édit. 4.)

For my own part, making all due allowance for the inaccuracy of some of the reports, I think the possibility of the long bones being broken by the violent action of the muscles is sufficiently proved. I have never seen but one example; but it was an unequivocal one; I attended, for the late Mr. Ramsden, an exceedingly strong man, at Pentonville, who broke his os brachii in making

a powerful blow, although he missed his aim, and struck nothing at all. The whole limb was afterwards affected with vast swelling and inflammation.

3. SYMPTOMS OF FRACTURES.

The symptoms of fractures are: the pain and inability of the patient to move the limb; the change in its form, the shortening of it; the separation and inequalities of the ends of the fracture when the bone is superficial; and especially the crepitus or grating which may be both heard and felt when the ends of the broken bone are made to rub against each other.

Most of these symptoms, however, taken by themselves, are equivocal; the pain and inability to move may arise from a mere bruise, a dislocation or other cause; and even the crepitus, one of the most important signs, is simulated in some cases of dislocation in consequence of synovial effusion. On this point Sir A. Cooper remarks, speaking of dislocations, that "some time after the accident, it frequently happens that a sensation of crepitus is produced by the effusion of adhesive matter into the joint and surrounding bursæ; the synovia in which becomes inspissated and crackles under motion. But every practitioner ought to be able to distinguish this *crackling* from the *grating* crepitus of fracture." — (*On Dislocations, &c.*; ed. by Bransby Cooper, p. 4.)

Indeed, the signs of fractures are so exceedingly various, according to the bones which are the subject of injury, that it cannot be said that there is any one, which is invariably present and characteristically confined to them. The writers of systems of surgery usually notice loss of motion in the injured limb, deformity, swelling, tension, pain, &c. as forming the general diagnosis of fractures. However, it is easily comprehensible by any one acquainted with anatomy, that numerous fractures cannot prevent the motion of the part, nor occasion outward deformity; and every surgeon must know, that though at first there may be pain in the situation of a fracture, no inflammation, swelling, and tension can take place till after a certain period. There may be, however, a swelling produced in the first instance by extravasation of blood, or by displacement of the ends of the bone.

When, therefore, a limb is broken, and the event is not manifest from the distortion of the part, it is proper to trace with the fingers the outlines of the suspected bone: if it be the tibia, let the surgeon examine with his fingers whether any inequality can be discovered along the anterior surface, and along the sharp front edge of that bone. If it be the clavicle, let him trace the superficial course of the bone in the same attentive manner. Wherever any unusual pain occurs, or any unnatural irregularity appears, let him try if a grating or crepitus cannot be felt, on endeavouring to make one end of the suspected fracture rub against the other.

[It must be borne in mind, however, that in cases where the ends of the fracture have been separated from each other by the action of muscles, or any other cause, it will be impossible to feel a crepitus unless the surgeon so manages the limb as to bring them into contact. This is especially true of fractures of the cervix femoris within the capsular ligament, where the two pieces may be sepa-

rated from each other to the extent of an inch or more.]

When the humerus, or the os femoris, is the subject of inquiry, a crepitus is felt almost as soon as the limb is touched; and, in the case of the broken thigh, there is a considerable shortening of the extremity, except in a few cases of completely transverse fractures.

[Here again, in some cases of shortening, unless the fracture be very oblique, it may be necessary to draw down the limb to its proper length to render the crepitus distinct, as the sensation produced by the smooth periosteal surfaces of bones overlapping one another will not be by any means so evident as that occasioned by their fractured ends.]

When there are two bones, as in the leg and the fore-arm, and only one is broken, the other continues to prevent the limb from being shortened, and thrown out of its natural shape, so that a crepitus can only be felt by a very careful examination with the fingers. The difficulty of the diagnosis is increased when the surgeon is consulted late, and great swelling has come on. "Where is the surgeon," says Boyer, "that has not sometimes hesitated to deliver an opinion in certain cases of this description?" (*Malad. Chir.* t. iii. p. 27.)

When the injured limb is shortened, the surgeon, before pronouncing that such change proceeds from the passage of the fragments over each other, must be sure that the bones are not dislocated, and that the limb is not naturally shorter than the other, or is shortened in consequence of a previous fracture, that has been badly set.

In comparing the length of the lower extremities one should place the pelvis in a horizontal position, and put the two anterior superior spines of the ossa ilii in the same line: for, if these processes are not on a level, the limb, towards which the pelvis inclines, will seem longer than the opposite member.

The practitioner who is well acquainted with the anatomy of the limbs, and particularly with the mutual relations of the eminences of the bones to each other, will readily perceive the alterations produced by a fracture. Whenever, in consequence of a fall, or blow, a limb becomes concave at a part where it ought to be convex or straight, *et vice versâ*, the change of shape and direction must proceed from a fracture with displacement. The inner edge of the great toe, when the leg rests on a horizontal surface, should correspond with the inner edge of the knee-pan. If this natural relation be altered; if the inner edge of the great toe correspond with the outer edge of the knee-pan, there can be no doubt of the existence of a fracture of both bones of the leg. (*Boyer*, vol. cit. t. iii. p. 25.)

I am aware that considerable harm, and great unnecessary pain, have been occasioned by too much solicitude to feel the grating of fractured bones, and whenever the case is sufficiently evident to the eyes, the practitioner who gives way to this habit, at the expense of torture to the unfortunate patient, ought in my opinion to be severely censured. A fracture is an injury necessarily attended with a great deal of pain, and followed by more or less swelling and inflammation; and to increase these evils, by roughly or unnecessarily handling the part, is ignorant and cruel, and (if I may use the expression) unsurgical.

In some kinds of fractures the broken bone is so surrounded with thick fleshy parts that it is difficult to feel a crepitus, or ascertain the existence of the injury. Some fractures of the neck of the thigh-bone are cases illustrative of this observation. In very doubtful cases, the stethoscope has been proposed as a means of elucidating the diagnosis, and Lisfranc is said to have used it with success. (See *Edinb. Med. and Surg. Journ.* No. 78. p. 237.)

4. PROGNOSIS OF FRACTURES.

The prognosis of fractures varies, according to the kind of bone injured, what part of it is broken, the direction of the breach of continuity, and what other mischief complicates the case. Fractures of bones, which have many strong muscles inserted into them, are more difficult of cure than those of other bones, which have not so many powers attached to them capable of displacing the fragments.

A fracture of the middle part of a long bone is less dangerous than a similar injury near one of its joints, which may be followed by synovial inflammation and ankylosis. Thus, in a fracture of the thigh-bone, near the condyles, the inflammation and swelling extend to the knee-joint, which is affected with a degree of stiffness that continues for a long while, and sometimes cannot be entirely cured during life. The experiments of M. Cruveilhier prove that various forms of irritation will make the periosteum, ligaments, and cartilages ossify; and it has been ascertained, that in some cases of fracture near the joints the ligaments have sometimes been converted into bone. (See *Andral. Anat. Pathol.* t. i. p. 300.)

Inflammation of a joint, brought on by fracture, is attended with more severe symptoms, in proportion as the contusion has been more violent. In a fracture near an articulation, it is to be observed, also, that common splints have little command over the short fragment, so that it is often difficult with them to prevent displacement; and, with respect to transverse fractures of the neck of the thigh-bone *within the capsular ligament*, although the possibility of the reunion of such cases *by means of bony matter* is no longer a disputed point, the cure is more commonly effected only by means of a fibrous ligamentous substance.

When a bone is fractured in several places, the case is more serious, and the difficulty of cure greater. But the accident is still worse when a limb is fractured in two different places at once; as, for instance, in the thigh and leg. Here, without the assistance of a double oblique plane, or M'Intyre's excellent apparatus, it would be almost impossible to reduce the fracture of the thigh and maintain the reduction well, so as to preserve the natural length of the limb.

Oblique fractures are more troublesome and difficult of cure than transverse ones, because an oblique surface does not resist the retraction of the lower portion of the broken bone, and consequently the ends of the fracture are kept duly applied to each other with difficulty.

Fractures, complicated with violent contusion of the soft parts, or with a wound, rendering them *compound*, are much more dangerous than others free from such accidents. The bad symptoms, which render compound fractures so dangerous, are of many kinds: hæmorrhage; violent and

extensive inflammation of the limb, either phlegmonous or erysipelatous; delirium and fever; large abscesses; gangrene; &c. Fractures of the leg are generally more serious than similar injuries of the upper extremity. The wound of a large artery may add considerably to the danger of a fracture.

In a debilitated old man, or an unhealthy subject, or a constitution predisposed to inflammation, particularly erysipelas, or to violent derangement of the nervous system, a fracture is less likely to end well than in a healthy child, or a strong young person, or one of good constitution. In extreme old age the cure of a fracture is always more difficult, and sometimes impossible. (*Boyer*, t. iii. p. 32.) Scurvy certainly retards the formation of callus, and, as I have already noticed, even produces its absorption again.

Fabricius Hildanus has cited two cases which tend to prove that the union of fractures is retarded by pregnancy. (*Cent.* 5. obs. 87. *Cent.* 6. obs. 68.) Alanson has also related a case in which the union, which had been delayed during pregnancy, took place after delivery (*Med. Obs. and Inq.* vol. iv. No. 37.); and Werner has published an account of a fracture of the radius in a pregnant woman, where the cure was apparently retarded for a long time by this circumstance, and though the union took place previously to delivery, the callus was not very firm till after that event. (*Richter*, *Bibl.* b. xi. p. 591.)

Other observations, however, have shown that though this may occasionally happen, yet that it is by no means invariably the case. Some years ago, I attended, for Mr. Ramsden, a woman in a court leading out of St. Paul's Churchyard, who broke both bones of her leg when she was several months gone with child. Her pregnancy, however, did not appear to be at all unfavourable to the cure, as it followed in the usual time. "It is not generally settled," says a modern writer, "whether pregnancy should be accounted a complication. I, as well as some other practitioners, have seen a pregnant woman get well of a simple fracture in the ordinary time." (*Leveillé*, *Nouvelle Doctrine Chir.* t. ii. p. 159. And in another place he says, "*Contre l'opinion de Fabrice Hildan, l'expérience m'a prouvé que, chez les femmes grosses, le cal était aussi prompt à se former, que chez toute autre personne.*" (*Op. cit.* t. ii. p. 172.) The experience of Boyer also tends to prove that pregnancy does not generally prevent the union of fractures. (See *Mal. Chir.* t. iii. p. 32.)

The cases in which fractures remain disunited will be considered in a future section.

5. TREATMENT OF FRACTURES IN GENERAL.

The treatment embraces three principal indications. The first is to reduce the pieces of bone into their natural situation. The second is to secure and keep them in this state. And the third is to prevent any unpleasant symptoms likely to arise, and relieve them if they come on.

The first indication is only applicable to cases attended with displacement; for when the fragments are not out of their relative position, the surgeon must strictly refrain from all avoidable disturbance of the limb. His interference should then be limited to putting up the fracture, resisting the accession of unfavourable symptoms, and removing them, if possible, after they have taken place.

Reduction.—The means employed for the reduction of fractures in general are chiefly three, viz. *extension*, *counter-extension*, and *coaptation*, or *setting*. But, as Boyer remarks, these means should vary according to the species of displacement; and surgical writers have generalised too much in representing them all three as necessary for the reduction of every kind of fracture. In fact, there are several cases in which extension and counter-extension are positively useless; of this nature are fractures of the patella and olecranon, where the displacement consists of a separation of the fragments. Here the reduction may be accomplished, by putting the limb in a position in which the muscles attached to the upper part of the bone are relaxed, and then pushing the upper fragment into contact with the lower.

Extension signifies the act of pulling the broken part in a direction from the trunk, with the view of bringing the ends of the fracture into their natural situation. By counter-extension, surgeons imply the act of making extension in the opposite direction, in order to hinder the limb, or even the whole body, from being drawn along by the extending power, which would then be unavailing.

It was formerly recommended to apply the extending force to the lower fragment, and the counter-extension to the upper one. Such practice, indeed, was advised by Mr. Pott, and is still generally preferred in this country; but upon the continent it has been abandoned. The objections made to it by Boyer are: first, that it is frequently difficult, and sometimes impossible, to take hold of the two fragments; as, for example, when the neck of the thigh-bone is broken. Secondly, that by applying the extension and counter-extension to the broken bone itself, most of the muscles which surround it are compressed, and such compression produces in these organs a spasmodic contraction which often renders the extension and counter-extension useless, and sometimes even hurtful. (*Mal. Chir.* t. iii. p. 34.) The French surgeons, therefore, apply the extending force to that part of the limb which is articulated with the lower fragment, and the counter-extension to that which is articulated with the upper. For instance, in a fracture of the leg, the extending means act upon the foot, and the counter-extending upon the thigh; and in a fracture of the thigh the extension is applied to the leg, while the counter-extending power fixes the pelvis.

One circumstance must here occur to the mind of the surgical reader. In this country it is properly inculcated that one of the first principles to be attended to in the reduction of fractures is to put the limb in such a position as will relax the most powerful muscles connected with the broken bone; because these muscles principally impede the reduction and disturb the ends of the fracture. But in the French mode of making the extension and counter-extension, how can this grand principle be conveniently fulfilled? If the extending and counter-extending means are not to be applied to the broken bone itself, but to others which are articulated with it, the limb must of necessity be kept in a straight posture at the time of reducing the fracture; for were the limb placed in a half-bent state, the extension and counter-extension, as practised by the continental surgeons, would not be in the same line, and, therefore,

less efficiently and readily accomplished. If it be advantageous to bend the limb at the time of reducing a fracture, the French mode of practising extension and counter-extension may not be the best. I am not, however, one of those surgeons who are entirely blinded with the idea of the possibility of relaxing the whole of the muscles connected with the broken bone by merely bending the limb. On the contrary, I am convinced with Desault, that in general what is gained by the relaxation of some muscles, is lost by the tension of others. But where it is possible to relax by a certain posture the set of muscles most capable of preventing the reduction and disturbing the coaptation of a fracture, that posture I would select. Thus in a fracture of the leg the strong muscles of the calf undeniably possess this power, and the bent position which relaxes them appears to me, therefore, generally the most judicious and advantageous, not only during the reduction, but during the whole treatment of the case.

It is difficult to lay down rules respecting the precise degree of force which should be used in making extension; for it must vary in different cases, according to the species of displacement, and the number and power of the muscles concerned in producing it. In transverse fractures, displaced only according to the diameter of the bone, a very moderate extension suffices, as it is merely practised with a view of lessening the friction and pressure of the surfaces of the fracture against one another. But whatever be the direction of the fracture, when the fragments pass over each other, the extension and counter-extension should be such as to remove the shortening of the limb, and overcome the force of those muscles which, after all attention has been paid to their relaxation, still oppose the reduction. Extension, however, ought never to be practised in a violent and sudden way; but in as gradual a manner as possible, the utmost care being taken not to shake, nor even move, the limb any more than can be avoided. When the practitioner extends a broken member all at once violently, he excites the muscles to strong spasmodic action, and there is some danger of lacerating them, because their fibres are not allowed the requisite time to yield to the force which elongates them. The extension is to begin in the direction of the lower fragment, and be continued in that which is natural to the body of the bone.

In every case of fracture with displacement, as soon as the necessary extension has been made, the surgeon is to endeavour to place the ends of the broken bone in their natural situation: this is termed *coaptation*, or *setting*. This operation is to be undertaken in different ways, according to the species of displacement, and the practitioner can almost always execute it by acting upon the lower fragment, without applying his fingers directly to the fracture itself, in order to regulate the contact of the extremities of the bone. When, however, it is judged necessary for this purpose to touch the broken part itself, it should be done with the utmost gentleness, so as to avoid pressing the soft parts against the points and splinters of bone.

Although the reduction of fractures may in general be accomplished with tolerable facility, it sometimes happens that the first attempts fail. This is occasionally ascribable to the employment of too much force and too little management, in

making the extension, whereby the muscles are irritated, and act so powerfully that the design of the surgeon is completely frustrated. Here the grand means of success is putting the limb into such a position as will relax the most powerful muscles which oppose the reduction. Sometimes, however, the irritable and convulsive state of the muscles is not the effect of any wrong mode of proceeding on the part of the surgeon, but arises from the alarm, pain, and injury caused by the accident itself, the comminuted state of the bone, the irritation of spicula, or the very oblique direction of the fracture. Here relaxing the muscles is also the most likely method of removing the difficulty. In short, now that the utility of paying attention to this principle is universally known in the profession, a fracture is rarely met with which cannot be immediately reduced, particularly if opium be given. But supposing the bone cannot be made to lie well at first, it will easily be made to do so in the course of a few days, when the tendency to spasm has diminished, and the pain and first irritation have subsided. Only let the surgeon watch and regulate the position of the limb about this period, and the cure will be completed without any deformity.

Of the means for keeping Fractures reduced.—After the bones have been put into their natural situation, time alone would complete their cure, were there not in the muscles a continual propensity to displace the ends of the fracture again. In cases of fracture the muscles are often affected with involuntary spasmodic action, by which the broken part would certainly be displaced, were no measures taken to maintain the extremities of the broken bone in contact. Besides, the patient, in easing himself, coughing, sneezing, &c. must unavoidably subject the limb to a degree of motion, by which the coaptation would be altogether destroyed. Hence the necessity of employing means for fixing the broken limb so effectually that it may continue perfectly motionless during the whole time requisite for the union of the fracture. The means employed for the fulfilment of this indication are: an advantageous position, quietude, bandages, splints, and various kinds of apparatus.

In the treatment of all fractures, the position of the part, and indeed of the whole body, is a thing of material importance. Whenever the case is a fracture of the lower extremities, the patient should lie strictly in bed until the callus is completely formed and strong. It is likewise an advantage not to have the bed too wide, because the surgeon and assistants can then more conveniently get at any part of the limb. As feather-beds are too yielding, a horse-hair mattress is preferable. Boyer, indeed, is so impressed with the utility of letting the patient lie upon a surface which will not sink, that he recommends two mattresses to be used, and a board to be laid under the upper one, from the hip to beyond the patient's foot. (*Mal. Chir.* p. 39. vol. iii.)

Generally the most favourable position for a fractured limb is that in which all the muscles, passing over the fracture and extending either to the lower fragment, or to that part of the limb which is articulated with it, are equally relaxed. The injured limb should also have firm support at every point, and its position ought to be regulated, so that not only this object be carefully fulfilled, but at the same time the chance of displacement from

the action of the muscles, or the weight of the body, or part itself, may be diminished as much as possible.

The natural, or rather the most easy, position of the limb, is that which is usually chosen by a person who reposes himself, or who is sleeping; for then all motion is suspended, and every part assumes that posture which is most congenial to it. In this condition the limbs are not extended, nor yet entirely bent; but only in a moderate state of flexion. Hence, Boyer remarks, that a half-bent position of the limbs is that which is most natural, and that in which all the muscles enjoy an equal degree of relaxation, and, consequently, that it is, generally speaking, the best for fractures. This posture, which was recommended by Hippocrates and Galen, has been highly extolled by Pott, who appears to have exaggerated its advantages. Considered in a general way, it is without contradiction preferable to every other position of the limb; but its employment should be liable to exceptions, as will be noticed in treating of particular fractures. (See *Traité des Mal. Chir.* t. viii. p. 40.)

In whatever position a broken limb is placed, it should bear, throughout its whole length, equally and perpendicularly upon the surface on which it lies, and not be only partially supported. When, for example, only the extremities of a fractured limb rest upon the bed, the weight of the limb itself will make it bend in the situation of the fracture. The limb will also be rendered crooked, if the broken part be supported, while the extremities of the limb (especially the inferior) sink lower by their own weight. The displacement of the fracture is not the only inconvenience arising from the limb being laid upon a surface where it is not everywhere equally well supported. The parts which bear on this surface, experience a painful degree of pressure, which, if long continued, may produce inflammation, and even sloughing of the integuments. Thus, in fractures of the leg, gangrene of the heel has sometimes arisen entirely from this cause. Such inconveniences may often be prevented by laying a fractured limb on a surface of corresponding form; that is to say, on a surface which is depressed where the limb has projections, and rises where it presents depressions. The surface should not be so hard as to annoy the patient; yet it ought to be sufficiently firm not to yield to the weight of the limb and apparatus.

In whatever position fractured limbs are placed, they ought to be kept perfectly quiet during the whole time requisite for the union. If the broken bone be moved while the callus is forming, the surfaces of the fracture rub against each other, and the process is disturbed and retarded; and, indeed, sometimes by repeatedly moving the limb, the consolidation of fractures is entirely prevented.

In order to maintain the limb in the right position, and in a state of quietude, and to preserve the fragments in proper contact with respect to each other, the surgeon is to caution the patient to avoid moving more than can be helped, and every cause likely to subject the limb to any kind of shock or concussion is to be removed. But, in particular, it will be necessary to apply a retentive apparatus, usually consisting of bandages, splints, tapes, straps and buckles, soft pads, &c.

With respect to bandages, the common roller answers for fractures of the humerus, radius, ulna, and fibula. Indeed, when M'Intyre's apparatus is made use of, or Desault's method of treating a broken thigh is followed, it is the most eligible bandage for all simple fractures of the lower extremity, and even for some compound ones. But if a broken thigh or leg is to be treated according to Pott's directions, then the eighteen, or many-tailed bandage is necessary. The advantages of it are that, by means of it, all necessity is avoided of lifting up, and disturbing the limb, every time it is dressed, or every time the bandage loosens. Indeed, with it the leg or thigh need never once be removed during the cure from the pillow or splint on which it has been deposited.

The same advantage, however, is obtained with common rollers, when M'Intyre's apparatus is used, which, as well as the limb itself, is to be encircled by them. (See *Description of a Splint invented for the Treatment of Fractured Limbs by James M'Intyre*, 8vo. Newcastle, 1825.) In University College Hospital we dispense with the sock, and fix the limb with three rollers; one surrounds the upper part of the leg and the knee; another binds the foot to the foot-piece and encircles the ankle; and the third is applied to the central part of the leg, including the situation of the fracture. This last roller admits of being taken off, and the fracture, simple or compound, examined, without meddling with the other rollers, which steady the upper and lower parts of the leg, and therefore it does not undergo the slightest disturbance. On the whole, I cannot fancy that any apparatus for broken legs will ever fulfil its purposes better than that of Mr. M'Intyre, which has also the recommendation of great simplicity. A very cheap form of this apparatus has lately been contrived by Mr. Liston, the peculiarities of which are the omission of most of the thigh part, and the placing of an aperture at the point where the heel lies, so that the painful pressure on this part is considerably lessened. However, those surgeons who prefer to treat fractured thighs in the flexed position, with the patient on his back, will find M'Intyre's apparatus, as arranged by himself, exceedingly convenient.

Another surgeon of Newcastle, Mr. T. M. Greenhow, is also the inventor of an exceedingly ingenious apparatus for fractures of the lower extremity. It enables the surgeon to bring the whole circumference of a broken leg into view, after the fracture has been set, without the least movement or disturbance of any part of the limb. This, as every man of experience knows, is a great advantage in the treatment of compound fractures, where the application of dressings to the wound sufficiently often, the prompt discharge of abscesses, the preservation of the parts in a cleanly state, and the opportunity of inspecting the position of the ends of the fracture in the early stages of the formation of the callus, are objects contributing very essentially to the favourable progress and termination of these accidents. With this apparatus permanent extension either of the leg or thigh, if judged advisable, may be adopted, there being a contrivance for this object. One chief principle of Mr. Greenhow's apparatus is, that the limb remains supported in an iron frame-work, after everything else has been removed. (See *T. M. Greenhow's Description of an Apparatus intended to*

facilitate the Treatment of Fractures, &c. 8vo. Lond. 1833.)

In France, the preference is given to Scultetus's bandage in almost every instance where we employ the eighteen-tailed one, from which it principally differs in being composed of separate transverse pieces admitting of removal, so that when a part of the bandage is soiled it can be taken away, and a clean piece (first stitched to that which is about to be removed), drawn under the limb, without disturbing the whole of the dressings. Dupuytren was partial to this bandage, not only in cases of compound fracture, but others where a frequent change of parts of the bandage was rendered necessary by the discharge.

As a general remark, we may say, that some apparatus of the foregoing kinds, a double oblique plane, or else splints, are unquestionably the most efficient of all the applications made to a broken limb, with the view of keeping the ends of the fracture steady, and in a proper state of contact.

"Splints," says Pott, "are generally made of pasteboard, wood, or some resisting kind of stuff, and are ordered to be applied lengthways on the broken limb; in some cases three, in others four; for the more steady and quiet detention of the fracture.

"That splints, properly made and judiciously applied, are very serviceable, is beyond all doubt; but their utility depends much on their size, and the manner in which they are applied.

"The true and proper use of splints is to preserve steadiness in the whole limb, without compressing the fracture at all. By the former they become very assistant to the curative intention: by the latter they are very capable of causing pain and other inconveniences; at the same time that they cannot, in the nature of things, contribute to the steadiness of the limb.

"In order to be of any real use at all, splints should, in the case of a broken leg, reach above the knee, and below the ankle; should be only two in number, and should be so guarded with tow, rag, or cotton, that they should press only on the joints, and not at all on the fracture.

"By this they become really serviceable; but a short splint, which extends only a little above and a little below the fracture, and does not take in the two joints, is an absurdity, and what is worse, it is a mischievous absurdity.

"By pressing on both joints, they keep not only them, but the foot steady; by pressing on the fracture only, they cannot retain it in its place, if the foot be in the smallest degree displaced; but they may, and frequently do, occasion mischief, by rudely pressing the parts covering the fracture against the edges and inequalities of it."—(See *Pott's Chir. Works*, vol. i. p. 298, &c. edit. 1808.)

Splints, double oblique planes, and other kinds of support for broken limbs, must always be lined with pads of tow, oat-chaff, or other soft materials, for otherwise their pressure would cause severe pain, inflammation, ulceration, and even sloughing.

Assalini strongly disapproves of the employment of all tight bandages, and of covering the whole of a broken limb with splints. In a case of transverse fracture of the patella, he laid the limb upon a concave splint, the shape of which was adapted to the under surface of a part of the leg and thigh.

No bandage was used, merely two leathern straps, which crossed upon the knee, and included the fractured bone. A perfect bony union was thus easily effected. Assalini afterwards extended the use of a concave splint, applied under the limb, to fractures of the leg and thigh. In the first of these cases, however, only the thigh is received in the hollow splint, and from this two lateral splints go along the leg. The apparatus has also a kind of sole for the support of the foot. As this simple contrivance is fastened with a very few straps, and no plasters or bandages are used, the surgeon has constantly a view of the whole front of the limb, and of the fractured part of it. In compound fractures, he covers the wound with linen compresses, wet with cold water. (*Manuale di Chirurgia, Parte prime*, 1812.) See SPLINT.

So convinced is Baron Larrey of the advantage of keeping broken limbs perfectly motionless, after they have been properly set, that he sometimes employs an apparatus which moulds itself to the shape of the limb, then hardens, and remains applied during the whole of the treatment, unless circumstances call for its earlier removal. The apparatus is made by wetting the pads, compresses, and bandages in a lotion, containing the acetate of lead and white of egg, which, when it has dried, leaves the apparatus sufficiently hard and stiff to afford full support and steadiness to the limb, with the advantage of being most perfectly accommodated to the exterior of it. This plan is followed, not merely in simple, but compound fractures, and when there is a necessity for removing the patient any distance, is found by Larrey highly expedient.

[An apparatus of this nature, "*appareil inamovible*," is now in very common use in the treatment of fractures. One of the most strenuous advocates of the method is M. Seutin of Brussels, and thick starch is the material which he employs to stiffen the apparatus. A dry roller is first applied round the fractured limb, underneath which layers of cotton-wool may be placed to protect the prominences of the limb from injurious pressure. The outer surface of the bandage is then smeared with the starch, and two splints of pasteboard, softened by soaking in water, are placed one on each side of the limb. The pasteboard should be torn rather than cut, in order that its edges, when it dries, may be less sharp and cutting. The pasteboard is to be retained in its place and moulded to the shape of the limb by another bandage, and this also is to be covered by layers of starch, laid on smoothly with the hand or with a brush. When the apparatus becomes dry a firm and solid case is obtained, and the patient may be allowed, in fractures of the lower extremity, to leave his bed and walk about on crutches, without danger of displacing the fracture. The drying is not complete for thirty-six or forty-eight hours, and during that time it is necessary to pay careful attention to the position of the limb, as the apparatus does not yet possess the requisite firmness to prevent displacement occurring. For this purpose temporary splints may be applied over the starched bandage, or, as M. Seutin prefers, a mould formed from an apparatus which has been already used in a similar case. When completely dry, M. Seutin divides it longitudinally with strong scissors or cutting pliers made for the purpose, and examines the limb to see whether any

undue pressure is occasioned at any point, and if this is the case, the fault is remedied by moistening it at that part and moulding it to the required shape. If the bandage is too tight it may be enlarged by separating the cut edges, and a piece of moistened pasteboard may be laid over the interval; if, on the other hand, it is too large, as is frequently the case from the shrinking of the limb, the edges can be cut away or can be made to overlap. When, by these manœuvres, a perfectly-fitting case has been obtained, it can be again firmly fixed by another bandage, which is to be covered, like the former ones, with starch. Many surgeons do not follow M. Sentin's practice in dividing the bandage for the purpose of inspecting the limb and adjusting it more exactly, but unless pain or great discomfort is complained of, allow it to remain undisturbed. The pasteboard splints also are only necessary; when very firm support is required; in the upper extremity, especially, two or three layers of bandage stiffened with starch are usually sufficient. M. Velpeau uses a solution of dextrine in preference to starch; it does not, however, possess any special advantage, excepting perhaps that it produces a somewhat firmer and harder case. Greater solidity may be easily obtained, if required, by adding a little powdered chalk to the starch solution.

It is an important question whether the "*unremovable apparatus*" should be applied immediately after the occurrence of the fracture, or whether it should be delayed until the swelling and inflammatory disturbance have subsided. Many continental surgeons, and among others M. Velpeau, advocate its immediate employment, and allege that the compression which it exercises is advantageous in preventing the development of inflammation, and also in procuring its resolution, if it does take place. Mr. Erichsen also speaks of having followed this practice in a large number of fractures of all kinds, and with very satisfactory results. The majority of English surgeons, however, prefer not to lose sight of the limb until the inflammatory swelling has subsided, and the parts about the fracture are in a quiescent state. The proper period will arrive sooner of course in some cases than in others, often at the end of four or five days in the upper extremity, often not for ten days or a fortnight in the lower extremity, or a longer period if the soft parts have been much contused. Used in this manner, the starched bandage is a very valuable aid in the treatment of fractures, and is productive of great comfort to the patient.]

In oblique fractures of the thigh, and sometimes even in those of the leg, the difficulty of accomplishing by the ordinary means a cure free from deformity, and especially without a shortening of the limb, led to the idea of employing *permanent extension*. This is effected by the operation of a bandage, or machine, which continually draws the fragments of the broken bone in contrary directions, at the same time that it restrains them from gliding over each other, and maintains them in contact during the whole time necessary for their union. In England this practice appears to have been chased away by Pott's dazzling theory of relaxing every muscle in such manner as to render it incapable of displacing an oblique fracture. Desault saw, however, great inconsistency in the doctrine of the possibility of relaxing the muscles, so as to incapacitate the whole set of them connected with a broken thigh; and he never ceased

to inculcate that a mechanical apparatus was the main thing by which the shortening of the limb was to be prevented. When we consider the treatment of fractured thighs, we shall find that the principle of permanent but moderate extension has had in France advocates of great talent and eminence, though it is a method to which many surgeons in this country for a long time entertained strong objections.

By means of permanent extension (observes Boyer), we not only succeed in uniting the fracture, while the limb preserves its natural length; but we afford the part a steadiness which is singularly favourable to the formation of the callus. In order to derive from permanent extension the utmost benefit, and render the method as little painful as possible, and supportable during the whole time of treatment, he recommended the machines and bandages to be constructed and applied conformably to the following rules.

We should avoid compressing the muscles which pass over the situation of the fracture, and the elongation of which organs is necessary to restore to the limb the length which it has lost by the gliding of the fragments over each other.

The extending and counter-extending force ought to be divided upon as large surfaces as possible.

The powers, making permanent extension, should act according to the direction of the axis of the broken bone.

The extension should be practised in as slow, gradual, and insensible a manner as possible.

Lastly: the parts, upon which the extending and counter-extending force acts, should be defended; and the compression, made by the tapes, or other pieces of the bandage and apparatus, ought to be equalised. (Mal. Chir. t. iii. p. 56, 59.)

If we consider the principles on which the mechanical means operate usefully in the treatment of different fractures, we shall find that they are various. For the most part, they have this effect by holding the ends of the fracture steadily in contact, maintaining the proper length of the limb, and hindering motion not only of the broken bone itself but of the joints connected with it, without which object being fulfilled, the fracture must always be liable to hurtful disturbance. In fractures of the shafts of the femur and humerus, and of the tibia, fibula and bones of the fore-arm, the apparatus acts beneficially in all or some of these ways; but, on certain occasions, it accomplishes its purpose, not by any direct action on the broken part of the limb itself, but by holding the limb in a particular position, and maintaining its due length. Thus, when the neck, or upper part of the thigh-bone is broken, the apparatus can have but an imperfect effect by its direct operation on the fracture, this portion of the bone being, as it were, not within its immediate grasp. But, by holding the limb in the right position, keeping it steady, and preventing its retraction, and the eversion or inversion of the foot, it accomplishes all which it is in the power of surgeons to do, especially if care be taken to let the pelvis and broken portion of the bone be so connected together by the apparatus, as to render them, as it were, one piece, only moveable together, in every movement of the patient, or change in the surface on which he is lying.

Frequently position does everything, without the slightest attempt to make any direct pressure on the fracture, or to act upon it immediately by

any other means. This is exemplified in fractures of the clavicle, cases in which, as well as several others, we see no splints at all employed, the requisite position of the arm and shoulder being maintained with a sling roller and pad in the axilla. Even in some cases where a splint is employed, it only operates by fixing the limb in the desirable position, as illustrated in fractures of the olecranon. In these last cases we also use mechanical means to keep the upper fragment from ascending too far; but, in other instances, position and quietude are the only principles in operation, as in the treatment of fractures of the coracoid and acromion processes of the scapula. Here the relaxation of the muscles by position, and quietude of the shoulder, are the only essential things to be attended to, and, whatever mechanical means are employed, are not designed to act directly on the broken parts of the bone.

Occasionally, the application of splints, bandages, and other mechanical means should be deferred. This is proper in fractures near joints, as of the olecranon, patella, &c. where the inflammation and swelling prohibit any compression of the part. Under such circumstances, the first indication is to subdue the inflammation by means of cold applications, bleeding, &c., care being taken, however, to lay the limb in a judicious position.

Means for preventing and removing the unfavourable symptoms liable to arise from fractures.—After having reduced the fracture, applied the apparatus for maintaining the reduction, and put the part in an advantageous position, the practitioner is to attend to another indication, viz. the prevention and removal of any unfavourable symptoms.

With the exception of a few simple fractures of the upper extremity, it is proper to allow for the first few days only very low diet. When the patient is young and strong, and the swelling and inflammation considerable, venesection may possibly in some cases be required. In other circumstances, it should be dispensed with, because it is well known that, for the quick formation of callus, by which the fracture is to be united, strength and a vigorous circulation are highly favourable. The patient may be permitted to drink as often, and as much as he likes, of any cooling acid beverage. The low diet is only to be continued the first few days, unless great inflammation arise; for experience proves that the method, when too much prolonged, has bad effects, and tends, on the same principle as bleeding, to retard the union of the fracture.

Costiveness is to be obviated by the use of mild aperient medicines. It must be confessed, however, that in fractures of the lower extremity, the disturbance of the limb caused by the patient's being obliged to move himself, after taking a purgative, is seriously objectionable; but perhaps in all, and certainly in some, habits, the neglect to open the bowels soon after the accident would have still more pernicious consequences. In order to lessen the disturbance, a bed-pan should be introduced under the patient. Here, also, I feel it my duty to recommend to the notice of the profession a very complete fracture-bed invented by my friend, Mr. Earle. One great convenience of this bed, the cost of which is moderate, is to enable the patient to void his *fæces* without the slightest change of position, or disturbance; an object effected by the simple contrivance of a little kind of trap, opening under the bed, out of which a

small portion of the mattress admits of being withdrawn, and a tin receptacle is placed for the reception of what is voided from the bowels and bladder. Some other advantages of this apparatus will be hereafter briefly mentioned.

With respect to external applications, we should carefully avoid using all such plasters and ointments as irritate the skin, or create a disagreeable itching; for they sometimes bring on erysipelas. In some cases, and especially in summer, it is a good plan for the first few days to wet the bandages with cold water; for in this way the tendency to inflammation and swelling may be considerably lessened. The surgeon, however, should recollect, that the bandage shrinks when wet, and may become so tight as to do harm, if not attended to. Solutions of the acetate of lead make the bandages stiff and hard; and as they are perhaps not more efficacious than cold water alone, the latter should be preferred.

When a fracture is well set, the position of the part right, and the bandage and splints neither too tight nor too slack, the less the broken bone is moved, and the less the apparatus and dressings are disturbed, the better. Sometimes, however, the practitioner is obliged to take off the splints, and undo the bandage, in order to ascertain that the ends of the fracture lie in even contact. Were he to leave the splints on the part too long, without ever being sure of this important point, he might find, when too late for alteration, that the fracture was in a state of displacement, and the limb seriously deformed. Hence, one reason for employing the eighteen-tailed bandage, or an apparatus like that of M'Intyre's, which admits of being opened without disturbing the limb, or even without lifting it from the surface upon which it has been deposited.

In fractures of the lower extremities, particularly of the legs, it sometimes happens, the first two or three nights after the reduction, that the limb is affected with spasms, which displace the ends of the bone. Here, if the patient be young and strong, let blood be taken from the arm, the bowels be emptied, and opium or morphia prescribed; strict attention being also paid to restore the ends of the fracture to a right position again. If they cannot be kept in exactly a good posture at first, they will admit of being so, after a few days, when the tendency to spasm has diminished.

When the callus has acquired some firmness, the patient should still keep the part or limb quiet, until the union is perfectly consolidated. And, in fractures of the lower extremity, even after the union has proceeded so far that the splints admit of being left off, the patient ought not to venture to get out of bed, or bear upon the limb, till several more days have elapsed.

All fractures, however simple and well treated they may be, are constantly followed by weakness and stiffness of the limb. These unpleasant consequences are the greater, the more violently the limb has been contused, the nearer the fracture is to a joint, and the longer the part has remained motionless, and without exercise. The stiffness always affects the inferior joint of the broken bone, much more than the superior. For the relief of these effects of fractures, it is customary to employ friction, liniments, emollient applications, cold washes and bathing; but sometimes, notwithstanding such remedies, the member does not

quickly recover its strength, but continues stiff and weak for a year, or even a longer time. The most effectual plans for the prevention of this state should therefore be resorted to early. These consist in making the joints nearest the fracture execute slight motions, as soon as the union is sufficiently advanced not to be in danger of interruption from this practice. A great deal of caution, however, is necessary in moving the part, and it is safer for the surgeon to superintend the business himself, than leave it to the patient, or others. One of the best proceedings also for the hindrance of much weakness and stiffness in the limb after a fracture, is to discontinue the splints and tight bandages immediately the state of the callus will allow. The manner in which their pressure retards the circulation, and prevents the action of the muscles, is one of the principal causes of the stiffness which sometimes ensues, and consequently, the sooner they can be safely left off, the sooner will the patient regain the free use of the limb.

In France, the chief division of fractures is into *simple* and *complicated*, which last includes, amongst many varieties, the cases which we name *compound*. We shall here briefly notice a few of the complications, and the particular treatment which they require.

Fractures (says Boyer) are always attended with a certain degree of contusion, which is constantly more severe in cases where the violence has acted directly on the situation of the fracture. But such contusion can only be regarded as a complication of the accident, when it exists in so violent a degree as to demand a different treatment from that which is employed in simple fractures.

In this circumstance, the splints and bandage should be applied rather slackly, and the latter ought to be wet with cold water, or some resolvent lotion. The patient is to be bled more or less freely, according to his age, the state of his constitution, and violence of the contusion. The next day, the splints and bandage should be opened; a thing highly necessary to be observed; for where it has been neglected, the limb has been known to mortify, in consequence of the swelling having rendered the bandage too tight. (*Boyer, Mal. Chir.* t. iii. p. 63, 64.)

In simple fractures it does not often happen that a large artery is wounded; but when the injury does occur, and a diffused aneurism takes place, the surgeon is to expose the vessel by an incision, and apply a ligature above and below the opening. We are to be careful, however, before resorting to the operation, that the tumor is not a venous extravasation, which may almost always be dissipated by resolvent applications.

Fractures are sometimes complicated with a dislocation. Here, if possible, the luxation should invariably be reduced before the fracture is set. The possibility of reducing the dislocation (says Boyer) depends upon the species of articulation, the situation of the fracture, and other circumstances of the case. When it is a ginglymoid joint, when the ligaments are lacerated, and the swelling is not considerable, the luxation may be reduced easily enough; but when it is an orbicular joint, surrounded by numerous muscles, and when the fracture is near the articulation, and situated below the dislocation, the reduction of the latter is impossible. The attempt, indeed, would be injurious, because the necessary extension could not act upon the

upper fragment; and were it to operate upon the lower, it could only have the effect of painfully stretching the muscles, and perhaps lacerating them. The fracture, therefore, should be at first attended to, and after its firm union an endeavour may be made to rectify the dislocation. Boyer conceives that there will be more probability of success when care is taken to move the limb gently, as soon as the state of the callus will permit it. He also recommends the employment of emollient relaxing applications. He confesses, however, that the attempt rarely succeeds after the perfect union of the fracture. There are, it is true, examples, in which old dislocations may be reduced; but these are cases which are not complicated with a fracture; an accident which always renders the muscles and ligaments so stiff that they cannot yield to the extension requisite for the reduction. "I do not know (says Boyer) that a luxation, complicated with fracture, has ever been reduced, when the nature of the joint, and the circumstances of the case, prevented the treatment from beginning with the reduction of dislocation." (*Mal. Chir.* t. iii. p. 79.) See DISLOCATIONS.

COMPOUND FRACTURES.

Here the first question is, whether an attempt should be made to save the limb? If the first opportunity of amputating be lost, there may *never* be another. *Inflammation* comes on, and the constitutional disturbance may prove fatal, and no second opportunity may present itself. In some cases, traumatic gangrene will invade the limb, and hardly leave time for the surgeon to amputate. Indeed, after it has once begun, so rapid is its progress that unless the operation be immediately performed, the patient's doom is sealed. Hence, in this kind of mortification, it is now a maxim not to wait for the red line of demarcation, but to remove the limb without the least delay, even though the mortification may be in a spreading state. With the exception of this case, if the first opportunity of amputating has been lost, the surgeon must wait until the constitutional disturbance has partly subsided before the knife can be used. This period may occur on the establishment of suppuration. But whether he ought now to amputate or not, will depend upon the extent and nature of the local injury; whether the soft parts are severely contused and lacerated—the bones crushed and comminuted—the degree of suppuration—the state of the pulse, &c. Under doubtful circumstances, the surgeon may yet be disposed to persevere in his endeavour to save the limb, and sometimes ultimately succeed in bringing the patient through all dangers; in extricating him from the weakening effects of repeated abscesses, profuse suppuration, &c. But in other instances, the long continuance of the suppuration—the presence and irritation of dead bone—the diseased state of all the cellular tissue—the implication, perhaps, of a neighbouring joint in the mischief, and the urgency of the hectic disturbance of the system, will compel the surgeon to amputate.

Supposing an attempt is to be made to save the limb, then the first indication is to reduce the fracture. For this purpose, lay the limb on the splint or apparatus, with pad, &c. and attend to the relaxation of muscles. When the protruding end of the bone cannot be returned, it is to be sawn off, or the wound enlarged.

When the fracture is *comminuted*, such fragments as are perfectly detached, quite exposed, and near the surface, are to be extracted.

The second indication is to bring the sides of the wound together, with an adhesive plaster, and after its edges have been approximated, the wound may be covered with wet lint; and if it unite, the compound fracture is at once converted into a simple one. With the view of keeping off inflammation, the bandages may be wetted with cold water.

In all leading points, the treatment of compound fractures is like that of simple, with the exception of measures called for by the wound itself; the higher degree of inflammation; the abscesses; the detached pieces of bone; the splinters, or sequestra; and the more severe constitutional disturbance. The same attention to keeping the ends of the bone in their proper position, and completely at rest, is even more urgently necessary.

As the presence of a suppurating wound, and the frequent formation of matter, render it indispensable to undo the bandage more frequently than in simple fractures, it should always be a maxim to employ such *splints, bandage, or apparatus* as will admit of this being done, as often as necessary, without any disturbance of the fracture.

An apparatus which will allow the surgeon to get at almost any part of the circumference of the limb, is particularly advantageous. Hence the superiority of M'Intyre's and Greenhow's apparatus, and the use of fracture-boxes.

While inflammation prevails in a high degree in the early stage of the case, the splints should not be tightly applied, and cold evaporating lotions and leeches may be of great service. Venesection may occasionally be beneficial when the patient is strong and full of blood; and saline purgatives and opium should be given.

One rule is to make early openings for the discharge of abscesses, and to let them be free and depending. Another maxim is to take away *sequestra* as soon as exfoliation is sufficiently advanced.

In tedious severe cases, patients sometimes fall victims to sloughing over the sacrum or trochanters. In the suppurative stage, attended with hectic symptoms, there is an obvious necessity for supporting the constitution, by means of tonics, sulphate of quinine especially, and light nutritious food and wine. In this stage, opium, pure air, and cleanliness will be of vast importance.

OF HÆMORRHAGE IN COMPOUND FRACTURES.

Profuse arterial bleeding is chiefly seen in compound fractures of the leg; but it may happen in those of the thigh or arm. If a wound of the anterior or posterior tibial artery be conjoined with a violent contusion and extensive *laceration of soft parts*, comminution of bone, or long fissures of it extending into or near the joint, amputation will generally be most prudent. In the opposite circumstances, the wound of the artery is not an adequate ground for removing the limb. In the treatment of such an accident, *pressure* and *cold* applications are insufficient, and it is indispensable to employ the ligature. Then the question is, whether the wounded part of the artery should be exposed and tied, or the *femoral* artery itself taken up.

Dupuytren and Delpech, instead of adding to the mechanical injury of textures already existing in the fractured part of the limb, advocated and practised the latter measure with decided success.

In this way the bleeding was commanded without any additional disturbance of the broken part of the limb. If we look over the particulars of cases where operations were practised to secure the anterior or posterior tibial artery, in compound fractures, we shall find that the result has commonly been mortification of the limb, and the patient's death. However, if the anterior tibial artery were wounded in the lower third of the leg, where its place is superficial, I think that the plan of securing it here would then be preferable to that of taking up the femoral artery.

OF THE FORMATION OF CALLUS, AND THE CONSOLIDATION OF FRACTURES.

In the treatment of fractures the whole business of the surgeon consists in putting the displaced extremities of the bone into their natural situation again; in keeping them in this position by means of a suitable apparatus; in endeavouring to avert unfavourable symptoms, and in adopting measures for their removal when they have actually occurred. The consolidation of a broken bone is the work of nature, and is effected by a process to which a good constitution, with as little disturbance of it as possible, is above all things propitious.

The process alluded to is that by which the new bony deposition, or the *callus*, as it is termed, which forms the uniting medium, is produced.

Surgical writers have been absurdly anxious to specify a determinate space of time which should be allowed for the completion of this process, as if it always went on in different cases with the same uninterrupted regularity. Forty days were often fixed upon as necessary for the purpose. This doctrine is not only false, but dangerous, inasmuch as patients have been thereby induced to suppose themselves cured before they were so in reality, and have consequently moved about too boldly, and thus run the risk of occasioning deformity, or a new fracture. It is impossible to determine precisely, and in a general way, the period requisite for the cure, because it differs according to a variety of circumstances.

1. *Age.* Fractures are consolidated, *cæteris paribus*, with more ease and quickness in young subjects than in adults or old persons. In general, also, the callus forms more speedily in proportion as the individual approaches to infancy. In two children whose arms had been broken in difficult labours, De la Motte found the humerus united in twelve days, by a very simple apparatus. In fact, at this period of life every part has a tendency to grow and develop itself, and the vitality of the bones is more active, their vascularity greater, their animal matter more abundant. On the contrary, in advanced age the parts have lost all disposition to development, and (to use the expression of Boyer) their vitality is nearly annihilated under the mass of phosphate of lime which accumulates in them.

2. *Constitution.* A fracture is united much sooner in a strong healthy person than a weak unhealthy subject. Sometimes the consolidation is prevented by some inexplicable unknown cause, nothing wrong being remarkable either in the constitution or the part.

3. *State of Health.* Fractures unite with more quickness and facility when the patient enjoys good health. Scurvy has a manifest and powerful effect in retarding the consolidation of fractures,

and even in causing the absorption of the callus several years after its formation, so that a bone becomes flexible again at the point where it was formerly broken. In Lord Anson's Voyage this phenomenon is particularly recorded. (See p. 142, edit. 15, in 8vo.) Langenbeck is acquainted with several cases in which the provisional callus, at the end of eight weeks, became again soft, and the bone flexible, in consequence of the patients being attacked with fevers or erysipelas. (*Neue Bibl.* b. i. p. 90.) Cancer, lues venerea, and rickets are also stated by surgical writers to obstruct, and sometimes hinder altogether, the formation of callus.

Pregnancy, as I have remarked in a preceding part of this article, has been sometimes found to retard the union of a fracture.

4. *Thickness of the Bone, and Weight which it has to support.* The bones are thicker and larger in proportion as they have a greater weight to bear, and as the muscles inserted into them are more powerful. It is observed, *cæteris paribus*, that the larger the bones are, the longer is the time requisite for their union. Thus, a broken thigh-bone is longer in growing together again than a fractured tibia; the tibia longer than the humerus, the bones of the fore-arm, clavicle, ribs, &c.

Besides the remarks made here, and in a preceding page, on the causes preventing the union of fractures, a few additional observations on the same subject will be introduced in the sequel of this article, when I speak of the modes of attempting the cure of old disunited fractures.

Three local circumstances were insisted upon by Boyer as necessary to obtain a firm callus, without deformity. 1. The two fragments must be possessed of sufficient vascularity. 2. The surfaces of the fracture must correspond. 3. They must be kept in a completely motionless state.

The two fragments must be sufficiently vascular. If one of them should be too scantily supplied with blood, the fracture would be incapable of union. This is what may happen in certain fractures of the neck of the femur, where the head of this bone is entirely detached, and the ligamentous substance which is reflected over its neck, and serves as its periosteum, is totally lacerated, as well as the vessels which ramify upon it. Hence, the upper fragment, lodged in the cotyloid cavity, may no longer receive from the vessels sent to it through the ligamentum teres a sufficiency of blood for the formation of callus with any degree of certainty. This is especially likely to be the case when the patient is far advanced in years, and the vessels considerably lessened in diameter. An adequate circulation must exist in both portions of bone; for without it the attempt at union will fail.

The surfaces of the fracture must correspond. This circumstance is not absolutely necessary for the consolidation of the fracture; but without it the formation of the callus will be slow and irregular. For instance, in a transverse fracture of the thigh-bone, the fragments, after being displaced according to the thickness of the bone, may undergo a second displacement, according to its length, by passing beyond each other. The surfaces of the fracture are then not at all in contact, and the portions of bone only touch each other by their sides. Here, at the end of the second month, the union will frequently have made but little progress; nor can the cure be accomplished without deformity and shortening of the limb.

The fragments must be retained in a motionless state. This condition is so essential to the formation of callus, that, if the ends of a fracture were daily moved, they could not unite. The two extremities of the bone would then heal separately, just like the sides of a wound which have not been put in contact.

Perhaps no subject has excited more discussion than the formation of callus. The ancients ascribed it to the extravasation of a gelatinous fluid, which was called the osseous juice, and which, becoming hard, served to unite the ends of the broken bone, just as glue serves to unite two pieces of wood. Hence, in order to favour the production of callus, they were in the habit of recommending their patients to eat abundantly of every sort of viscid farinaceous aliment, the glutinous parts of animals, and especially osteocolla, of which Fabricius Hildanus relates miracles.

According to Duhamel, callus is formed by the periosteum, which he regards as the organ of ossification. When a bone is fractured (says this naturalist), the periosteum of the two fragments first grows together, and then swells, and forms a circular rising round the fracture. The thickened membrane is converted into a gelatinous substance, which soon becomes cartilaginous. In this vessels are developed, and different points of ossification commence, which multiply and unite. Thus, when every part of the periosteum near the fracture is hardened and ossified, *this membrane is changed, as it were, into a sort of clasp, which extends over the two fragments, and holds them together.*

It was objected to Duhamel's theory, that, if a bone be slit longitudinally in the situation of a former fracture, the fragments are observed to have their substances blended completely together, and not simply to lie in contact in the manner of two pieces of wood placed end to end, and kept in contact by means of a clasp. Duhamel, with the view of obviating this difficulty, supposed that the periosteum elongated itself from the circumference towards the centre of the bone, and that such continuation of this membrane underwent the same changes as that portion which was contiguous to the fracture, and thus served to unite the ends of the fragments between which it was interposed. He admits also in some cases that the *internal periosteum, or medullary membrane, may furnish productions extending between the ends of the fracture*, like the continuation of the external periosteum with which they become connected. Lastly, he supposed that in young subjects, whose bones had not acquired their full degree of hardness, the cartilaginous part was capable of extension, and that, in cases of fracture, it contributed to the more perfect union of the fragments.

Boyer thought that Duhamel imputed too much to the periosteum; but that Haller and Dethleef were also wrong, when they supposed that an unorganised lymph could produce an organised substance by inspissation. (See *Le second Mémoire sur les Os, par M. Bordenave, recueilli et publié par M. Foucheroux*, p. 124.) It appeared to Boyer much more natural to believe that the gelatinous lymph already contains the rudiments of organisation, which become visible as they are developed; just as it is usually believed that the rudiments of all our organs are contained in the transparent mucilage of which the embryo seems to consist.

The experiments of Duhamel and Dethleef were carefully repeated by Bordenave, who ascertained several new and interesting facts. The result was the same in regard to the phenomena observed; but the explanation of them was different.

Instead of attributing the formation of callus to the periosteum, like Duhamel; or to the extravasation of lymph, or fibrine, like Dethleef; Bordenave conceived that broken bones unite again by a process analogous to that which nature employs for the union of the divided soft parts. His inference is principally founded on two facts generally admitted. 1st, That there is in the bones a vascular texture, designed to maintain the circulation in them. 2nd, That such texture dilates when fractures are uniting, as appears from the swelling in the situation of the fracture, without which swelling there could be no union. Bordenave further remarks, with Haller and Dethleef; 1st, That callus, at the commencement of its formation, appears to consist of a glutinous fluid effused from the ruptured vessels. 2nd, That this substance afterwards assumes the form of cartilage, to which certain vessels are distributed, which deposit the bony matter, and thus begin the generation of callus. 3rd, That the particles of bone, being all joined together, the callus changes into a porous substance, which in time becomes solid and compact, like the substance of bones.

John Hunter explained the formation of callus by the organisation of the extravasated blood, and its subsequent ossification. He noticed also the inflammation of the extremities of the bone, the softening and rounding of them, and the partial absorption of their earthy particles.

According to Mr. Howship, the first effect of fracture is the extravasation of blood between the fragments into the medullary cavity, and also into the periosteum, which is thus thickened. The blood coagulates, loses its colouring matter, becomes organised, assumes the appearance of cartilage, and is at length converted into bone. This latter change is first effected external to the fragments, and in the medullary canal, so that an osseous case is formed before the complete reunion of the fracture. (See *Med. Chir. Trans.* vols. vi. vii. and viii. and *G. Gulliver*, in *Edinb. Med. and Surg. Jour.* for July 1835. p. 44.) Mr. Howship's observations are interesting, as coinciding very much with those previously made by Duhamel, Villermé, Breschet, and Dupuytren.

The observations made by Baron Larrey lead him to reject as erroneous the doctrine which refers the production of callus to the periosteum, and he adopts the opinion that the union and reparation of bones are the work of their own vessels. He adverts to examples in which, after the use of the trephine in young subjects, the perforation becomes more or less closed by new bone, thrown out from the circumference towards the centre. Here, says he, the ossification assuredly can neither be referred to the pericranium, nor the dura mater. The first of these membranes has been extensively destroyed, and if the second were concerned, a vertical substance, shutting up the opening, would be apparent. In further support of his opinions, Baron Larrey cites the well-known celerity with which fractures of the lower jaw unite, on account of the great vascularity of that bone; and he believes, with Sir Astley Cooper, that if the ends of a fracture do not

touch, in consequence of loss of substance, the intervening space remains unfilled up by new bone; a position which seems rather repugnant to what he has said concerning the mode of reparation after the use of the trephine.

With respect to the alleged impossibility of union, when fractures are attended with loss of substance, Mr. Gulliver observes that the union of bone, under such circumstances, is common in the lower animals, and has been repeatedly observed in the human subject, of which a remarkable instance is recorded by M. Contevoz. (*Mem. de l'Acad. de Chir.*) "Professor Syme showed me a case in the Royal Infirmary of Edinburgh, in which he had removed from the tibia of an adult male about an inch of the entire diameter of the bone, which had been completely reproduced; and I saw in the practice of Dr. Bushe of New York, a similar example in the femur of a young man, which was not followed by a shortening of the limb equal to the length of that portion of the shaft of the bone removed by Dr. Bushe." (*Gulliver*, in *Edinb. Med. Journ.* No. 124, p. 46.) If any doubt could exist on this point, it would cease on our remembering the occasional cures of dis-united fractures effected by sawing off the ends of the bone.

For the most complete account of the process by which broken bones unite, we are indebted principally to MM. Villermé, Breschet, Sanson, Cruveilhier, and Dupuytren, all of whom, however, owe a great deal to their predecessors in the same field of inquiry, more especially to Duhamel. In 1808 Baron Dupuytren instituted certain experiments to determine the truth of the statements made on this subject by Bordenave and Bichat, but was surprised to find nothing to justify their accounts, and he was led to adopt other views, partly founded, however, on those of Duhamel. The process is far more complicated than represented by Bordenave and Hunter. Many years ago Sir Benjamin Brodie also made experiments upon animals with the view of elucidating this subject, and the preparations are still preserved. At that time he thought of publishing a paper on the union of fractures; but, before his investigations were completed, he found the whole matter so satisfactorily made out by Baron Dupuytren, that he was induced to relinquish the design. (See *London Med. Gaz.* for 1833-34, p. 54.) The results of Mr. Bransby Cooper's experiments seem also to agree very much with those arrived at by Dupuytren, due allowance being made for the greater celerity of the process in the bones of rabbits than in those of the adult human subject. (See *Guy's Hospital Reports*, part 4.) The researches of MM. Villermé, Dupuytren, and Breschet prove that all the old descriptions of the process were too limited and exclusive. When a bone is broken, the soft parts near it are torn and contused, and the vessels of these, as well as of the periosteum and medullary membrane, assist in the reparation. It has long been familiarly known that callus is not formed suddenly; that it requires more or less time for its production; and that the broken part of the bone only obtains solidity by degrees. Now, before the work of repair is complete, several changes happen, one after another, or in succession. Hence, the process is now usually divided by pathologists into four stages.

In the *first*, comprising a period of about ten

days from the time when the accident took place, if the injured parts are examined, blood is found to be extravasated around the ends of the fracture, between them, and even in the medullary canal. The ecchymosis may extend to parts far from the fracture. Considerable inflammation and swelling ensue at the irritated points. The muscular fibres are confounded with the inflamed cellular tissue, and very soon cannot be distinguished from other parts. The periosteum becomes red, swollen, and softened, and a reddish serous fluid is effused between it and the portions of the bone which it covers. The fibrous appearance of the ends of the bone disappears. The medullary membrane itself swells, inflames, and gradually obliterates the tube in the centre of the bone. The medulla acquires a greater consistence, and the portion of it in one fragment is conjoined with that of the other. If we look at what is passing between the ends of the fracture, we find that the coagulated blood between them is absorbed in a few days, and replaced by a gelatinous fluid; and between the fourth and the sixth day the surfaces of the fracture are sometimes, but not always, covered by a reddish, fleecy substance. (See Dupuytren, *Clinique. Chir.* t. iv. p. 132.)

In the *second stage*, extending from the tenth to the twenty-fifth day, the swelling of the soft parts becomes firmer, and every day more intimately adherent to the substance between the ends of the fracture; and the muscles resume their usual appearance. This *tumor of the callus*, as it is termed by Baron Dupuytren, now diminishes in extent, and becomes more distinct from the surrounding parts. Its texture is homogeneous, very like fibro-cartilage, and divided with difficulty. Its fibres are parallel to the axis of the bone. The swollen medullary membrane, transformed into a fibro-cartilaginous texture, progressively lessens the central cavity of the bone, and at length fills it up. The internal production, or peg (*cheville*) resulting from these organic changes, becomes blended on the level of the fracture with the substance interposed between the fragments. (See Dupuytren, *op. et t. cit.* p. 133.)

As the formation of the callus advances, other particularities are noticed, and these occur in what may be considered as the *third stage*, which begins about the twenty-fifth day, and is prolonged to the fortieth, or even the sixtieth. In weak constitutions the process is not finished till the end of the third month. The firm, homogeneous, fibrous mass, constituting what Dupuytren names the *tumor of the callus*, acquires by degrees a cartilaginous, and rather an osseous consistence. About the end of this period the fragments are placed in the centre of a solid ferule, which adheres to every point of their circumference. This kind of ferule, or clasp, the very same thing which was accurately described by Duhamel, is covered by thickened periosteum, which is united to that which invests the sound portions of the bone, and no external traces remain of the solution of continuity. The surrounding cellular tissue is yet stiff and indurated. The soft substance between the fragments has become denser and more adherent to the extremities of the bone; but it is still far from uniting them with any degree of perfection. The central peg, continuing to extend itself towards the ends of the fracture, rapidly assumes a greater consistence, and soon forms a very solid osseous cylinder. It

is commonly at this period that surgeons discontinue the apparatus; but the callus, now existing, is not to remain, and consequently Baron Dupuytren terms it the *provisional callus*.

Fourth stage. Between the third and the fifth, or sixth month, the tumor of the callus becomes gradually more compact; and the central ossification, or peg (*cheville*) undergoes the same transformation. The substance interposed between the fragments acquires all the organic characters and the consistence of the firm substance of bone, from which it is only distinguishable by its particular colour. It is this intervening substance, transformed into an osseous tissue, which makes what Baron Dupuytren has named the *definitive callus*.

Finally, the central ossification (*cheville*) assumes a lighter texture, cells are produced within it, and, after having been converted into a reticular texture, it disappears, leaving the central canal of the bone perfectly free again. After the restoration of the medullary canal, a medullary membrane, which invested the cells, becomes continuous with the membrane that lines it and secretes the medulla. Lastly, the external portion of the provisional callus (for the central ossification may be looked upon as another part of it) disappears.

As Dupuytren further explains, the differences of fractures must occasion slight varieties in the formation of the callus. Thus, when the two ends of the fracture pass over one another, the internal cylindrical ossification, or peg, is not formed; and the case is the same when the bone does not present a medullary canal.

This history of the process by which fractures unite must at once let us understand that the period of forty days, sometimes specified as the time requisite for the consolidation, is far from being sufficient, and that it should be much longer in oblique fractures, and those where the ends of the bone ride over one another.

The same history would lead us to expect what certain facts prove, that, down to a certain period, when a fracture has united with much deformity of the limb, the surgeon may safely make the callus yield, so as to bring the limb into a better shape. Dupuytren has recorded cases in which he accomplished this purpose in the leg, after the twenty-ninth and even the fifty-ninth day, and in which a deviation of the hand towards the radial side of the fore-arm was rectified as late as the twenty-fifth day. The advantage now spoken of may be obtained without breaking the callus, which is a substance endued with a certain degree of suppleness and elasticity. The fragments having been brought into a better position by the observance of the principles recommended to be attended to in the reduction of fractures generally, the improved situation of the fragments is to be secured by mechanical means. Thus, as Dupuytren remarks, supposing there is a projection made by the end of one, or those of both fragments, the limb is to be placed between two inflexible planes, which compress it in two diametrically opposite directions. As the projecting points receive the greatest pressure, they tend to return to the level of the rest of the bone. If, by means of pads, the projection is increased, while a vacancy is left at the opposite point, then the effects produced will be still more marked, and even carried so far as to cause deformity in the other direction. The same improvement may be

brought about even without acting directly on the seat of the fracture, by employing the lower fragment as a lever, and applying an apparatus, calculated to incline it in the direction that will bring it into a better position with respect to the upper fragment. (*Dupuytren, Clin. Chir. t. iv. p. 147.*) The apparatus should be put on more tightly than in a recent stage of fracture; but the manner in which the limb bears the pressure must be vigilantly attended to. So long as the deformity is not entirely corrected, the apparatus should be opened every third or fourth day, and fresh but gentle attempts at reduction made. Every little improvement made by each manual interference is then to be secured by means of the bandage and apparatus. In this way the natural shape of the limb will be gradually restored. The plan is not, however, to be continued too long, as it would altogether prevent union of the bone. Another maxim laid down by Dupuytren is, that, when the deformity has been considerable, the treatment after its removal should be continued as long as if the case were a recent fracture. (*Clin. Chir. t. iv. p. 146—151.*)

The *provisional callus*, then, differs from the definitive, not only in point of situation and time of its formation, and continuance, but in its inferior consistence and solidity. When completed, it only possesses the strength necessary to resist the moderate action of the muscles, and to support a certain weight. Nay, after the removal of the splints, it will sometimes yield to these forces, especially in oblique fractures.

The support of the provisional callus is frequently overcome by a blow or rough use of the limb. Sometimes it is weakened or destroyed by the influence of constitutional diseases, fever, &c.

The *definitive callus*, though less bulky, is harder, stronger, and more compact than the *provisional*. Hence, after the definitive callus has been completed, bones rarely or never break in the exact situation of the former fracture. Excepting in very aggravated forms of scurvy, I believe that the definitive callus is hardly ever disorganised and destroyed by the effects of constitutional diseases.

When the two ends of a fracture are in contact only at a point, it is here alone that the definitive callus can be produced; but, as a compensation, the external or provisional callus is then never entirely absorbed.

In fracture of the neck of the thigh-bone, entirely within the capsular ligament, the provisional callus cannot reach the fracture, and, if bony union follow, it is effected by a process within the bone itself. "The instances (says Mr. Mayo) in which union is effected through a process originating in the bone itself, are fractures of the cranium, and of the neck of the thigh-bone, within the capsular ligament. In the first of these cases no provisional callus is formed: in the second, the provisional callus has no means of reaching the fracture. It is difficult to explain why a provisional callus does not form about fractures of the cranial bones. The physical cause of this negative phenomenon is not known. The final cause, however, is evident. If a hard swelling, such as a provisional callus, were stretched as a ridge along the inner aspect of a cranial fracture, it would encroach upon the cranial cavity; and hemiplegia, epilepsy, or some other form of cerebral disorder would attend the

cure of every fracture of the skull. No callus therefore is formed. But the fracture, after a time, shows a disposition to unite through forces inherent in the bone itself, &c. In a fissure of the skull, examined some months after the injury, the only change apparent is the rounding of the edges externally. After a year or two the fissure is united at its internal or cerebral aspect. After the lapse of many years the narrowest part of the fissure is entirely filled up. In persons who have lived ten, twenty, or fifty years, after loss of portions of the cranium, the slow restoration of the bone appears to have been progressive for the whole period. In fifty years, a trephine hole is nearly closed by the shelving growth of bone from the margin towards the centre." (See *Mayo's Outlines of Human Pathology*, p. 8.) The causes of the difficulty of bringing about osseous union in such fractures of the neck of the femur as are entirely within the capsular ligament, will be hereafter considered.

When the ends of a fracture only touch laterally, as I have stated, there is strictly no provisional callus. The vessels of the adjoining cellular tissue, muscles and other textures, here greatly assist in the work of reparation. The side of one fragment becomes soldered to that of the other, and here the callus is permanent, or never removed. In such a case there is no internal cylindrical ossification; no *cheville*, as the French term it; because it would evidently be of no service.

In compound fractures, followed by suppuration, the bones remain disunited for many weeks. Here also no provisional callus is formed. The ends of the bones soften and granulate, and, in proportion as the secretion of pus subsides, the granulations begin to deposit the osseous matter, which is to constitute the uniting medium. This part of the subject was explained many years ago by John Hunter and the late Mr. Wilson. (*On the Skeleton, Diseases of Bones, &c. p. 233, 8vo. also Dict. des Sciences Med. t. xxxviii. p. 486.*)

Fractures of the patella, olecranon, condyles of femur, coronoid process of the ulna, acromion, and coronoid process of the jaw, are generally united by a ligamentous substance.

Broken cartilages, the cartilages of the ribs especially, and in some instances the thyroid or cricoid cartilages, do not unite by cartilage, but by means of osseous matter, deposited around the solution of continuity, in the manner of a provisional callus, which, however, is here permanent.

As the provisional callus in adults never begins to ossify before the tenth day, we know that, if great inflammation or other causes forbid the application of mechanical means during this period, no permanent deformity will be the result of deferring the employment of splints, bandages, &c. On this principle, and with the view of letting the limb get into a more favourable state to bear the pressure of mechanical means, some surgeons do not usually apply any apparatus during this stage. In infancy, however, where the callus is completed with surprising quickness, it is desirable always to set the fracture without delay.

[The more recent investigations of Mr. Stanley and Mr. Paget have led them to form conclusions on the subject of the union of fractured bones somewhat different from those of Dupuytren, and especially as regards the formation of provisional callus in the human subject. Mr. Stanley, while admitting and confirming the views

above expressed as to the union of fractured bones in animals, thinks that in man, where the ends of a fracture are kept perfectly at rest, there is no provisional deposition of callus, as in animals, which is afterwards to be absorbed, but that the union takes place by direct ossification of the substance effused between the ends of the fractured bone. He admits, however, that a provisional callus is formed in the human subject after fractures of the ribs, and also that in cases where the bone cannot be kept at rest, the irritation may occasion the deposition of an ensheathing osseous substance answering all the purposes of a provisional callus, as in animals, but not, like it, previously cartilaginous or deposited between the periosteum and bone, but infiltrated more indiscriminately into all the surrounding tissues in consequence of the irritation produced by the movements of the fracture. Mr. Stanley thus states his conclusions: "The undisturbed ends of a fractured bone in man unite by the medium deposited between its fractured surfaces; that the amount of adventitious osseous deposit accompanying the reparation of a fracture is proportionate to the degree of irritation which, from the unquietness of the ends of the bone, is excited in the surrounding parts; that the seat of this deposit is the periosteum and cellular tissue adjacent to it; but that the characters of this deposit are wholly distinct from those of the provisional callus in animals. Such will be the explanation of the seemingly irregular osseous deposits around fractured bones. The interpretation of other osseous productions of well-defined shape and texture, found upon this or that side of a fractured bone, or filling up the hollows between its displaced portions, must be sought for by observing in what directions such additions of support and strength were required." (See *Illustrations of the Diseases and Injuries of the Bones*, p. 29, 1849.)

Mr. Paget coincides with the views of Mr. Stanley on this point, and considers that "the normal mode of repair in the fractures of human bones is that which is accomplished by 'intermediate callus.' The principal features of difference between it and union by provisional callus are, (1.) that the reparative material or callus is placed chiefly or only between the fragments, not around them. (2.) That when ossified, it is not a provisional, but a permanent bond of union for them. (3.) That the part of it which is external to the wall of bone is not exclusively, or even as if with preference, placed between the bone and the periosteum, but rather in the tissue of the periosteum, or indifferently either in it, beneath it, or external to it." Mr. Paget thinks it possible that when the fragments are placed in close apposition and correspondence, that they may be joined by immediate union (that is, that they may be united without any new material being formed for their connection; a continuity of tissue and blood-vessels being restored, as in the cases of healing by immediate union of soft parts), but if this do not happen, a thin layer of reparative material is deposited between them; it does not in any direction exceed the extent of the fracture; neither does it, in more than a trivial degree, occupy the medullary canal; but, being inlaid between the fragments, and there ossifying, it restores their continuity. The process may be compared with that of union by primary adhesion. If, however, as more commonly happens, the fragments at certain parts project more or less one be-

yond the other, the reparative material is, as in the former case, inlaid between them, but is also in larger quantities placed in the angles at which the fragments overhang one another, but never to the extent of forming a complete ensheathing callus, excepting in the ribs, and more rarely the clavicle. "It is deposited where it is most wanted for the strengthening of the bone, and in quantity as well as position, is adapted to the exigencies of the case, so as to restore, as much as may be, the original condition and capacities of the bone." If it be inquired why this difference should exist in the corresponding processes in man and in other animals, Mr. Paget thinks it must be ascribed principally to two causes, namely, the quietude in which fractures in our bones are maintained, and the naturally greater tendency to the formation of new bone which animals always manifest. In answer to the statement that an ensheathing callus can often be felt during life, he says, "The deception is produced either by thickening and induration of the soft parts around the fracture, or by the two overlapping ends of the fragments being grasped at once, or much more rarely, by new bone accumulated about the fragments in consequence of inflammation." (See *Lectures on Surgical Pathology*, vol. i. p. 251.)

Mr. Paget has examined the changes which the effused reparative substance undergoes previous to its conversion into perfect bone, and has found that those changes are by no means the same in all cases, but that the lymph, previous to its ossification, may form itself into perfect cartilage, into fibro cartilage, into pure fibrous tissue, or into the rudimental forms of the latter tissue, viz. nucleated cells or nucleated blastema. In animals, perfect cartilage with cells, intercellular substances, and all the characters of pure foetal cartilage may be produced. Mr. Paget has not found the same process in the human subject, but thinks it might occur in favourable instances of simple fracture in children. In youths and adults he has met only with varieties of fibrous cartilage, presenting numerous gradations from the fibrous towards the perfect cartilaginous structure.

The new bone, through whichever mode it is formed, quickly acquires its proper microscopic characters. Its corpuscles or lacunæ, being first of simple round or oval shape, and then becoming jagged at their edges, subsequently acquire their canals, which appear to be gradually hollowed out in the preformed bone, as minute channels communicating with one or more of the lacunæ. The laminated canals for the blood vessels are of later formation. (*Paget*, op. cit. p. 246.)]

OF THE CONDUCT TO BE ADOPTED AT THE ORDINARY PERIOD OF THE CONSOLIDATION OF FRACTURES; AND OF UNUNITED FRACTURES, AND FALSE JOINTS.

When the requisite time for a broken bone to become firmly united has elapsed, it is proper to examine carefully and cautiously the place of the fracture, in order to learn whether the callus has acquired a suitable degree of strength. If the bone should be found to bend in the least at the injured part, the callus is not sufficiently strong, and the limb should be immediately put up in the apparatus again, with the view of preventing a new fracture, or, at all events, deformity.

For the same reason the patient should not be

allowed to make free use of his limb as soon as the fracture has united. In fractures of the lower extremity he ought to use crutches, and only let the weight of the trunk by degrees bear upon the injured limb. From neglect of this precaution the callus has been known to be absorbed, the limb to be shortened, and the patient become a cripple. An accidental slip may also produce the fracture again; for the provisional callus, so far from being firmer than the rest of the bone, is at first considerably weaker.

That the state of the constitution has vast influence over the process by which broken bones are reunited, is unquestionable. Schmucker found the formation of callus, even in the most simple fractures, sometimes delayed eight months, and in one example, more than a year; but all the patients were unhealthy. (*Vermischte Chir. Schriften*, b. i. p. 26.)

There are certain indescribable constitutions, in which bones, particularly the humerus, will not unite again after being broken. These temperaments are also exceedingly various; at least, I infer so from two subjects, to whom I paid particular attention. One was a strong robust man, whose chief peculiarity seemed to be his indifference to pain: the ends of his broken humerus were cut down to, turned out, and sawn off by Mr. Long, in St. Bartholomew's Hospital, and the limb was afterwards put in splints, and taken the greatest care of; but no union followed. The other case was a broken tibia and fibula, which remained disunited for about four months, but afterwards grew together. The latter subject was a complete instance of hypochondriasis. I afterwards saw a woman, under Sir James Earle, in the above hospital, whose humerus did not unite, though it had been broken several months. Every attempt to move the bone occasioned excruciating torture. The woman died of some illness in the hospital, and on dissecting the arm, the cause of the fracture not having united was found to arise from the upper sharp-pointed extremity of the lower portion of the broken bone having been forcibly drawn up by the muscles, and penetrated the substance of the biceps, in which it still remained. I am indebted to Mr. Earle for the description of the appearance in the dissection, and I do not know that this kind of impediment to the union of a fracture has been noticed by any earlier writer than Mr. Charles White, who appears to have conceived the possibility of the occurrence. (*Cases in Surgery*, p. 70, edit. 1770.)

Sir Benjamin Brodie attributes the want of union mostly to the state of the constitution. "A gentleman (says he), was growing fat, and not liking to do so, he placed himself on a very spare diet, though accustomed to good living previously. After six months of starvation, he broke his arm, and the bone would not unite. I saw him many months afterwards, and there was scarcely any union even by soft substance. Another patient, about whom I was consulted, a lady, was growing fat, and thought she would also prevent it by pursuing a similar system of diet. Some months afterwards she broke her arm, and union did not take place." A man broke his thigh and remained ten days without any action of the bowels: no union of the fracture ensued. The same distinguished surgeon adverts to other facts, which tend to prove, that tight bandaging and other cir-

cumstances, unfavourable to a free circulation in the limb, may prevent union. (See *Lond. Med. Gaz.* for 1833-34, p. 57.)

It is observed by Larrey that the gunshot wounds of the extremities, complicated with fracture, especially with that of the humerus, received by the soldiers of the French army in Syria, were almost all followed by the formation of accidental joints. The two fragments of the broken bone continued moveable, their asperities and projecting angles having been destroyed by friction, and their ends being rounded and covered with a cartilaginous substance, so as to facilitate the motions which the patients executed in various directions, in an imperfect manner and without pain. Larrey acquaints us that many invalids were sent back to France with such infirmity.

"I ascribe," he says, "the causes of these accidental articulations:

"1. To the continual motion, to which the wounded soldiers were exposed after their departure from Syria till their arrival in Egypt, in consequence of their having been obliged either to walk this journey on foot, or to be carried on beasts.

"2. To the bad quality of the food, and the brackish water, which the men were under the necessity of drinking in this painful journey.

"3. To the state of the atmosphere of Syria, almost entirely destitute of vital air, and impregnated with pernicious gases, issuing from the numerous marshes, near which we were a long while stationed.

"All these causes may have prevented the formation of callus, either by diminishing the quantity of the phosphate of lime, or moving the bones out of that state of coaptation in which they should constantly lie in order to unite.

"Bandages, embrocations, rest, and regimen proved quite ineffectual." (*Larrey, Mém. de Chir. Mil.* t. ii. p. 131, 132. *Langenbeck, N. Bibl.* b. i. p. 81.)

The presence of an ulcer, a sinus, loose splinters of bone, a necrosis, or other suppurating disease, near a fracture, is a circumstance that often seriously retards or completely prevents the formation of callus. How frequently have I noticed in compound fractures, that, while the wound suppurates largely, and while there are spicula and dead portions of bone unextracted, no solid union takes place; but that as soon as the wound, ulcer, or sinus admits of being healed and the suppuration ceases, ossification goes on in the most favourable manner.

With respect to the union of broken bones being prevented by disease, Sir Benjamin Brodie believes that this *may* be the case where there is an abscess in the bone, a necrosis, or some other conditions. "I know, however," he observes, "that the rule is not *absolute*; for, in a great many instances, where the bone is diseased, it will unite perfectly. I had a patient, who had disease of the bones, whether it arose from syphilis, mercury, or a cachectic state of the constitution, I cannot say; however, some of the bones had nodes upon them, and were very much enlarged. The principal enlargement was in one of the clavicles. There was a portion of this bone enlarged, and much diseased besides. This man, in using his arm, broke the collar-bone, the fracture going through the diseased part. I bound up his

arm, and concluded, that there would be no union ; but to my surprise, it united quite as soon as ordinary fractures. Women, labouring under cancer of the breast, are very liable to a similar disease of different bones in the body. Sometimes this disease, which is indicated by pains, like those of rheumatism, will affect nearly the whole of the bones, which then become brittle, and very liable to break. I first observed this fact, many years ago, in the case of an old woman, who was dying of cancer, and who, in turning one day in bed, broke the thigh-bone. I concluded that the broken bone would not unite ; but union took place as well as under ordinary circumstances. I attended a lady, two years ago, who had cancer of the breast, and pains in the limbs, indicating cancerous disease of the bones. There was a scirrhus affection of the collar-bone ; and one day, in moving her arm, the collar-bone was broken ; but it united, just as if it had been a healthy bone." (*Sir B. Brodie, in Lond. Med. Gaz. for 1833-34, p. 56.*) The truth of the latter statement has been proved in the case of a woman with a cancerous breast who has been a patient in University College Hospital more than once under Mr. Liston, for spontaneous fractures, which have always united again tolerably well. I was once called to see a coachman for a retention of urine, dependent on a cancerous disease of the bladder. A few days afterwards his thigh-bone broke as he was turning in bed ; and in the course of another week he died. The *post-mortem* examination detected a scirrhus tumor under the periosteum, surrounding the fractured part of the bone ; and one of the ribs, which had given way, was similarly encompassed. The history of the case is recorded in the *Med. Chir. Trans.* vol. xvii. and the specimens are preserved in University College Museum.

According to Boyer, the ends of the fracture, which are sometimes rounded, and sometimes pointed, are connected together by a cellular and ligamentous substance. But their surfaces are not covered by a smooth cartilaginous matter, nor is there constantly a capsular ligament. "I am convinced of this fact, by the dissection of several ununited fractures, the fragments of which are preserved in my museum." (*Boyer, t. iii. p. 94.*) And, in another place, the same Professor, speaking of these false joints, remarks : "I repeat that I have never found, in their structure, anything which could be compared with an articulation ; neither capsular ligament, nor smooth cartilaginous surfaces. On the contrary, I have invariably found, in the false joints of the thigh-bone and humerus, which I have had opportunities of dissecting, a fibrous ligamentous substance, extending from one fragment to the other, and it is very probable, that, with some modifications, it is the same with all the other cases, which I have not seen.

On this subject, Langenbeck observes, "When the parts are incessantly moved, the end of one fragment becomes excavated, in the form of an articular cavity. I have in my possession (says he) a lower jaw, and an olecranon, the fractures of which are not united. For the connecting medium, nature has provided a white substance, resembling ligament. I have also seen an articular connection established in the body of the thigh-bone subsequently to a fracture." (*Neue Bibl. b. i. p. 93.*)

In the Hunterian Collection may be seen a

false joint in the bones of the fore-arm, where the resemblance to a natural articulation was greater than what Boyer has seen in other situations.

According to Professor Sharpey, the connection is mostly by means of a tough, fibrous, ligamentous-looking mass ; and the nearest approximation to a new articulation which occurs, consists in the existence of cavities, more or less extensive, between the fibres of this connecting substance. (*See Syme's Principles, ed. ii. p. 161.*) The bond of union is stated to differ from ordinary ligament in presenting no fibrous appearance. Sir Benjamin Brodie, who has made this remark, coincides with Boyer, with regard to the ordinary mode of connection ; admitting, however, the occasional formation of a new, or false joint, where "the rounded ends of the bones are covered by a thin ligamentous substance, and the inner surface of the capsule is lined by a smooth membrane, like the synovial membrane, and capable of secreting synovia." (*See Lond. Med. Gaz. for 1833-34, p. 57.*)

A valuable dissertation on false joints was published by Reisseisen, entitled "*De Articulationibus analogis, quæ Fracturis Ossium superveniunt.*"

[Rokitansky, who has more recently investigated this subject, describes these unnatural joints resulting from fracture as of two kinds : "one more or less resembling a synarthrosis, the other like a diarthrosis, and accordingly, in its proper sense, a new joint.

"In the former case, the fractured ends of the bone are held together by a ligamentous tissue. Either a disc of ligament, the thickness of which may vary, is interposed between them, and allows but of little movement ; or, as occurs when there has been loss of substance, either from injury, absorption of the fractured ends or otherwise, ligamentous bands connect the fragments, and allow them to move freely on each other. The connecting tissue appears to be nothing more than the intermediate substance, which has failed to become transformed into the secondary callus and remains in its first state.

"In the second case, a ligamentous articular capsule is formed, and is lined by a smooth membrane which secretes synovia. The fractured surfaces adapt themselves to each other and become covered with a layer of tissue, which is fibro-ligamentous, or more or less fibro-cartilaginous, or which resembles and sometimes (Howship) really is cartilage. They may articulate immediately with one another, or may have between them an intervening layer of ligament, which corresponds to an inter-articular cartilage ; and their movement upon each other is more or less free, according to the size of the articular capsule, and the form of the articulating surfaces. These last are sometimes horizontal and smooth ; they glide over each other and allow of restricted motion : sometimes one surface becomes convex and the other concave : sometimes both are rounded off, and, lying within a capacious articular capsule far apart, they come in contact only during particular movements. The articular capsule is the product of the inflammation of the soft parts : the cartilaginous layer, which covers the ends of the bone, is secondary callus arrested in its metamorphosis and converted into a fibroid tissue. The other ligamentous cords which are sometimes present, and the structures resembling an inter-articular cartilage,

are remnants of the intermediate substance. Both forms of new joint, but more particularly the synarthrodial form, have an analogue in the lateral new joints sometimes found between the masses of callus which are thrown out around two adjoining fractured bones. In the fore-arm and leg, and between the ribs, for instance, new joints are sometimes met with between the masses of callus after fractures have united." (*Rokitansky, Patholog. Anat.* vol. iii. p. 216, *Sydenham Society's Translation.*)]

A false joint in the arm, or fore-arm, does not absolutely prevent the motion of the limb, which may yet be of considerable use; but, when the disease is in the thigh or leg, the member cannot support the weight of the body, and the patient is unable to walk without crutches.

The diversity of causes which may be concerned in preventing the union of fractures, plainly shows that the treatment should be different in different cases.

When the want of union is ascribable to the ends of the fracture not being in a state of coaptation, and to their having been moved about too frequently, the obvious indications are, to set the fracture better, and to take adequate measures for keeping its extremities in contact and perfectly motionless.

If the union has been prevented by a portion of muscle, or other soft part, getting between the ends of the bone, the only means of affording a chance of union would be cutting through the integuments, removing the displaced soft parts, and placing the ends of the bone in contact. (*Wardrop, in Med. Chir. Trans.* vol. v. p. 363.)

When the advanced age of the patient seems to be the cause of the union not taking place, the application of the proper apparatus is to be continued a considerable time, since experience proves that in old subjects the cure of fractures often requires many months. In such examples, also, tonic and cordial medicines, with a nutritive diet, are highly proper.

Anything in the state of the constitution likely to account for the want of union should be removed or rectified. "One patient may require to be put upon a better diet; another may require purgative medicine; another may stand in need of tonics. Mr. Wilson used to relate the case of a woman who was a dram-drinker, and who broke her leg. At first she was not allowed to take her customary drams, and the bones showed no disposition to unite. At last, she was allowed to take a certain quantity of spirit, and union took place immediately." (*Brodie, op. et vol. cit.* p. 58.)

When several months have elapsed since the accident, and there is reason to apprehend that a preternatural joint or a ligamentous union has taken place, a variety of local plans have been proposed.

Here I may remark that no severe operation will be justifiable, unless the inconvenience, arising from the want of bony union, be considerable. If a broken rib were not to unite, by osseous matter, it would be of little consequence. I opened an old man who was in this state, yet he had never complained of it, nor indeed had he ever been aware of it. Sir Benjamin Brodie has a specimen of a joint, formed in a rib after fracture; and the patient was believed to have

suffered little or no inconvenience from it. (See *Lond. Med. Gaz.* for 1833-34, p. 58.)

The most ancient method of treatment is that of forcibly rubbing the ends of the fracture against each other, so as to make them inflame, and take on a disposition to form callus. This plan was recommended by Hunter, and has had the approbation of many other distinguished modern practitioners. In a disunited fracture of the leg or thigh, Mr. Hunter used to let the patient get up, and attempt to walk with the splints on the limb, so that the requisite irritation might be produced. The idea of exciting a degree of inflammation in the situation of the fracture, certainly appears rational, and the practice has been attended with a degree of success. Mr. White records an example, in which he cured a broken thigh on this principle, a strong leather case having been made for the limb. (*Cases in Surgery*, p. 75.) A broken tibia, treated on similar principles, is mentioned by Mr. Amesbury. (*On Fractures*, p. 211, ed. ii.) The method is spoken of in Celsus: *si vetustas occupavit, membrum extendendum est ut aliquid lædatur: ossa inter se manu dimovenda, ut concurrendo exasperentur, et ut si quid pingue est, eradatur, totumque id quasi recens fiat, &c.*

I have seen cases in which the union was thus brought about. In numerous instances (says Sir Benjamin Brodie), I have known patients in the hospital kept in bed for ten weeks, and even longer, without union taking place. A splint has then been bound on each side of the limb; we have put the patient on crutches, made him walk about, put the limb to the ground, and exercise it with the splint on, and the fracture has become united. Then in other cases I have applied blisters to fractures which were slow in uniting: but, if this method is to be useful, it must be tried in eight or ten weeks after the accident. (*Brodie, in Med. Gaz.* for 1833-34, p. 58.)

The foregoing treatment, however, is only likely to answer before a new joint, or a ligamentous connection, has been completely formed, and when the limb has hitherto been kept motionless.

When the case is old, and there are grounds for believing that a new articulation, or ligamentous connection, has taken place, we are advised to cut down to the ends of the bone, rasp or saw them off, and then treat the limb just as if the case were a recent compound fracture.

Sir Everard Home used to mention the case of a man with ununited fracture of the humerus, who was under Mr. Hunter's care. There was an artificial joint, and Mr. Hunter made an incision into it, and then having introduced a spatula, he irritated the whole surface of the artificial joint. This brought on considerable inflammation, which ended in ankylosis, and the patient was cured. (*Sir B. Brodie, in Med. Gaz.* for 1833-34, p. 58.)

This bold practice was first suggested by Mr. C. White. "Robert Elliott, of Eyham, in Derbyshire, a very healthful boy, nine years old, had the misfortune, about Midsummer, in the year 1759, by a fall, to fracture the humerus, near the middle of the bone. He was immediately taken to a bone-setter in that neighbourhood, who applied a bandage and splints to his arm, and treated him as properly," says Mr. White, "as I suppose he was capable of, for two or three months. His endeavours, however, were by no means productive of the desired effect, the bones not being at all

united. A surgeon of eminence, in Bakewell, was afterwards called in; but as he soon found he could be of no service to him, and as the case was very curious, he advised the lad's friends to send him to the infirmary at Manchester. He was accordingly brought thither the Christmas following, and admitted an in-patient. Upon examination, we found it to be a simple oblique fracture, and that the ends of the bone rode over each other: his arm was become not only entirely useless, but even a burden to him, and not likely to be otherwise, as there was little probability that it could ever unite, it being now six months since the accident happened.

"Amputation was therefore proposed as the only method of relief: but I could not give my consent to it, for as the boy was young, and had a good constitution, it was hardly possible that it could be owing to any fault in the solids or fluids, but that either nature was disappointed in her work by frequent friction, while the callus was forming, or rather that the oblique ends of the bone, being sharp, had divided a part of a muscle, and some portion of it had probably insinuated itself betwixt the two ends of the bone, preventing their union. Whichever of these might be the case, I was of opinion," continues Mr. White, "that he might be relieved by the following operation, viz. by making a longitudinal incision down to the bone, by bringing out one of the ends of it, which might be done with great ease, as the arm was flexible, and cutting it off, either by the saw or cutting pincers; then by bringing out the other, and cutting off that likewise, and afterwards by replacing them end to end, and treating the whole as a compound fracture.

"The objections, made by the other gentlemen concerned, to this proposal, were, first, the danger of wounding the humeral artery by the knife; secondly, the laceration of the artery by bringing out the ends of the bones; and thirdly, that we had no authority for such an operation. As to the first, that was easily obviated, by making the incision on the side of the arm opposite to the humeral artery. The place of election appeared to me to be at the external and lower edge of the deltoid muscle, as the fracture was very near to the insertion of that muscle into the humerus; the danger of wounding the vessel not only being by that means avoided, but, after the operation, while the patient was confined to his bed, the matter would be prevented from lodging, and the wound be easily come at, to renew the dressings. The second objection will not appear to be very great, when we consider that, in compound fractures, the bone is frequently thrust with great violence through the integuments, and seldom attended with laceration of any considerable artery; and as this would be done with great caution, that danger would appear very trifling. The third and last objection is no more than a general one to all improvements.

"This method which I have been proposing," says Mr. White, "was at last resolved upon, and I assisted in the operation, which was performed by a gentleman of great abilities in his profession, on January 3, in the present year (1760). The patient did not lose above a spoonful of blood in the operation, though the tourniquet was not made use of. When the operation and dressings were finished, the limb was placed in a fracture box, contrived on purpose, the lad confined to his bed,

and the rest of the treatment was nothing different from that of a compound fracture.

"The wound was nearly healed in a fortnight's time, when an erysipelas came on, and spread itself all over the arm, attended with some degree of swelling: this, by fomentations, and the antiphlogistic method, soon went off, and the cure proceeded happily, without any other interruption. In about six weeks after the operation, the callus began to form, and is now quite firm. The arm is as long as the other, but somewhat smaller, in consequence of such long-continued bandages: he daily acquires strength in it, and will soon be fit to be discharged." (*Cases in Surgery*, p. 69, &c.)

In another instance of a broken tibia, which continued disunited an extraordinary length of time, Mr. White practised an operation, somewhat similar to the foregoing one, with complete success. He made a longitudinal incision, about four inches in length, through the integuments, which covered the fracture. By the application of a trephine, he cut off the upper end of the bone, and as the lower end could not be easily sawn off, he contented himself with scraping it. In the course of the subsequent treatment, he had occasion to take off, with the cutting pincers, a small angle of tibia, and to touch the lower part of the bone with the butter of antimony, as well as to introduce the same caustic between the extremities of the fracture, in order to destroy a substance which intervened. A trifling exfoliation followed. In twelve weeks the bone was firmly united. (*Op. cit.* p. 81, 82.)

Besides Mr. White's cases, there are now some other instances upon record, where the operation, which he first proposed, has succeeded. In the year 1813, Langenbeck operated upon a humerus in the foregoing manner, and the result was perfectly successful. The ununited fracture was situated at the insertion of the deltoid. (*Neue Bibl.* b. i. p. 95.) Mr. Rowlands, of Chester, by a similar operation, believed that he had cured a fractured thigh, which had lost all disposition to unite. (*See Med. Chir. Trans.* vol. ii. p. 47.) I understand, however, from Sir Benjamin Brodie, that the subject of this operation lately died, and that on examination of the broken part of the limb, there was no bony union. Viguerie, surgeon to the Hôtel-Dieu, at Toulouse, practised Mr. White's operation with success. (*See Larrey, Mém. de Chir. Militaire*, t. ii. a. 132.)

On the other hand, the operation has frequently failed. In the instance in which I saw it executed on the humerus by Mr. Long, in St. Bartholomew's Hospital, it did not answer, though the ends of the bone were most fairly sawn off, and the case treated with particular care and skill. Boyer states that he once performed the same operation in a similar case; but that it had not the desired effect. (*Traité des Mal. Chir.* t. iii. p. 110.) Dr. Physick, of New York, when he was a student in 1785, saw this proceeding unsuccessfully adopted in a case where the humerus remained disunited. (*See Medical Repository*, vol. i. *New York*, 1804.) Besides these examples, I have heard of others, in which Mr. Cline, Mr. Green (*Med. Chirurg. Review*, February 1828; and *Lond. Medical Gazette*, p. 357), and other practitioners tried the experiment with no better success. What is still more discouraging, the operation has sometimes proved fatal. (*Richerand, Nosogr. Chir.* t. iii. p.

39, ed. 2. *Larrey, Mém. de Chirurgie Militaire*, t. ii. p. 132.)

Baron Dupuytren deemed the removal of one end of the fracture sufficient, and gives two cases in which the plan succeeded; one of a thigh-bone, the other of a lower jaw. In the latter instance, however, he scraped away the ligamentous texture from the anterior fragment. (See *Journ. Univ. des Sciences Méd.* t. ix. 1820; and *Clin. Chir.* t. iv. p. 667, 8vo. Paris, 1834.)

The difficulties, the danger, and the frequent ill success of White's operation, had rendered another mode of treatment extremely desirable, when Dr. Physick of New York suggested the plan of introducing a seton through the preternatural joint, with the view of exciting inflammation, and bringing about the union of the bone. It was, in fact, a practice founded on Hunter's principles. Dr. Physick had an opportunity of performing the new operation on the 18th of December, 1802, in an example of disunited humerus, twenty months after the occurrence of the accident. "Before passing the needle (says Dr. Physick), I desired the assistants to make some extension of the arm, in order that the seton might be introduced as much as possible between the ends of the bone. Some lint and a pledget were applied to the orifices made by the seton-needle, and secured by a roller. The patient suffered very little pain from the operation. After a few days the inflammation (which was not greater than what is commonly excited by a similar operation through the flesh of any other part) was succeeded by a moderate suppuration. The arm was now again extended, and splints applied. The dressings were renewed daily for twelve weeks, during which time no amendment was perceived; but soon afterwards the bending of the arm at the fracture was observed not to be so easy as it had been, and the patient complained of much more pain than usual, whenever an attempt was made to bend it at that place. From this time the formation of the new bony union went on rapidly, and on the 4th of May, 1803, was so perfectly completed that the patient could move his arm in all directions as well as before the accident happened. The seton was now removed, and the small sores occasioned by it healed up entirely in a few days. On the 28th of May, 1803, he was discharged from the hospital perfectly well, and he has since repeatedly told me his arm is as strong as ever it was." (*Physick, in Medical Repository*, vol. i. *New York*) In the *London Medical Repository* for Aug. 1823, a case is also noticed, in which Dr. Physick cured an ununited fracture of the lower jaw by means of a seton.

On this subject an interesting memoir was read by Laroche to the *Ecole de Médecine* at Paris (*Germinal*, an 13). It was entitled "*Dissertation sur la non-réunion de quelques fractures, et en particulier de celles du bras, et sur un moyen nouveau de guérir les fausses articulations qui en résultent.*" The author of this production affirms, that when he was at Augsberg, he saw Baron Percy, then with the army of the Rhine, pass a seton through the imperfectly healed cicatrix of a compound fracture of the thigh, which fracture seemed to have lost all disposition to unite. The method answered so well, that in two months the patient was able to walk without crutches.

Sir Benjamin Brodie has successfully employed the seton in a case of ununited fracture of the thigh.

The patient was a boy about 13. (See *Med. Chir. Trans.* vol. v. p. 387, &c.)

[He has subsequently recorded three other cases in which he employed this method. One of these three, a case of fractured clavicle of some years' standing, succeeded perfectly, but the other two failed. In one of them, a man with ununited fracture of the thigh, the seton caused so much constitutional disturbance that it became necessary to remove it. In the other, although it was left in for several months, it produced no beneficial effect. (See *Lectures on Pathology and Surgery*, p. 131, 1846.)]

In this country the same operation has been practised for the cure of a disunited humerus by Mr. Stansfield of Leeds. (See *op. cit.* vol. vii. p. 103, &c.) It appears, also, that Sir Charles Bell applied the method to a fracture of the leg, at the time when M. Roux was in England. The patient was a child six years old, and the broken bones had continued without union three years. The case had been originally mistaken by some unskilful surgeon for a mere contusion. The result is not stated. (*Parallèle de la Chir. Angloise, &c.* p. 195.) In University College Hospital, Mr. Liston lately employed a seton for an ununited fracture of the radius and ulna. The result was successful in reference to the latter bone. After cutting down to the fracture, he destroys the ligamentous connections as much as possible, and then passes the seton, which he takes out again sooner than is usually done.

We are not to expect that Dr. Physick's operation will succeed in every instance. Like most other surgical means, it is liable to occasional failures, amongst which, I believe, we must include the attempt, made on a disunited thigh by Mr. Wardrop (see *Med. Chir. Trans.* vol. v. p. 365), though a partial amendment is mentioned. In a case recorded by Mr. Amesbury, the seton did not answer. Mr. A. C. Hutchinson was also obliged to take out the seton, in a case of ununited humerus, and only partial benefit was effected. (See *Practical Obs.* p. 339, ed. 2.) Three instances of failure were seen by Mr. Amesbury (*On Fractures*, p. 224), and an additional one has been recorded by Mr. Earle. (See *Med. Chir. Trans.* vol. xii. p. 195.)

In the same case, and also in another, which I saw under this gentleman's care, the plan of cutting down to the ends of the fracture, and rubbing them with caustic potash, was tried, but without success.

The result of the practice with the seton is, that it has sometimes succeeded in the upper extremities; but that, where it has been performed on the lower ones, so far as Sir Benjamin Brodie has been able to ascertain, it has only answered in a single instance, which was that of a patient under him in St. George's Hospital. "Dr. Dorsey (who was Dr. Physick's nephew), in the last letter which I had from him before his death, informed me as the result of the operations with the seton in the United States, that it had generally succeeded in the upper limbs, but that it had always failed in the lower." He added that "in the former case it was often necessary to keep the seton in for several months" (*op. et vol. cit.*) M. Portal, however, surgeon to the Palermo Hospital, cured by the seton an ununited fracture of the upper third of the femur in a child two years old. (See *Archives*

Gén. Juillet 1835.) An instance of an ununited fracture of the tibia was also successfully treated with a seton by Dr. Browne. (See *Dublin Hospital Reports*, vol. iv. p. 320.) A very similar case was published by Mr. Boggie. (See *Med. Chir. Trans.* vol. vii.) Dr. Mott has treated eleven cases of ununited fractures in this manner. Of these, three were of the femur; three of the tibia, and five of the humerus. In all, the plan is stated to have succeeded perfectly, except in three of the humerus, which were afterwards cured by sawing off the ends of the bones. (*Amer. Journ.*) These results are different from those which might have been expected from the investigations of Sir Benjamin Brodie, and the statements of others, concerning the success of sawing off the ends of the bone.

Instead of several of the foregoing severe and often unsuccessful plans, Mr. Amesbury has tried the influence of local pressure and rest. He maintains the ends of the fracture closely pressed together, the pressure, when the fracture is transverse, operating longitudinally, and when oblique, transversely. On this subject, Sir Benjamin Brodie observes, "I do not know that this firm pressure produces the union of the bone by a process at all like that which takes place in the first instance after fracture. I think it more likely that it causes the surfaces to grow together without the provisional callus being formed on the outside. However that may be, I know that in several cases it has succeeded. I have attended two cases with Mr. Amesbury in which this plan was adopted, and in which it succeeded perfectly. I had a patient in St. George's Hospital on whom I tried this method of treatment, and in that case also it succeeded, so that at the end of some weeks the fractured bone, which had been ununited for many months, became completely consolidated. The pressure must here be considerable, so as to give the patient a good deal of pain, yet not sufficient to do him injury." Sir Benjamin Brodie, however, has known of several cases in which this method has failed; but notwithstanding this fact, he pronounces it to be on the whole a more successful plan than any other. A short sling, pads, and a particular apparatus are used accordingly. (*On Fractures*, p. 236.) Mr. Buchanan, of Hull, has related two cases in which the union of fractures followed a perseverance in the application of tincture of iodine. (*On Diseases of Joints*, p. 75.)

[Instead of the seton, Dieffenbach has proposed to cut down upon and expose one or both ends of the fracture, and then to bore holes in the bone, into which he inserts pegs of ivory, which are to be left in for several weeks in the hope of inducing the necessary amount of reparative action. This method has been adopted occasionally in this country by Messrs. Stanley, Hey, Bowman, and others, in some cases with complete, in others with partial, success.]

Subcutaneous sections in the neighbourhood of the fracture have been practised with success by Mr. Miller, of Edinburgh, and the method is worth trying before resorting to the more serious practice of the seton, or of resection of the ends of the bones. The inflammation thus excited is of the adhesive instead of the suppurative kind, and is therefore attended with little or no risk, while in some cases it may produce sufficient irritation to cause the required effusion of osseous matter.]

OF PARTICULAR FRACTURES.

FRACTURES OF THE NASAL BONES.

These bones, from their situation, are much exposed to external violence. The fragments may be displaced, or not. In order to replace them, the surgeon must pass a female catheter, a ring-handled forceps, or any such instrument, into the nostrils, and, using it as a lever, push the fragments outwards; while with the index finger of the left hand, he prevents them from being pushed out too far. When the fragments are disposed to fall inwards again, some authors advise supporting them with an elastic gum canula, or lint, introduced into the nostril; but I am inclined to believe with Sir C. Bell, that no tubes can be employed so as to support the broken bones; and when these have been replaced, they will not readily change their position, as they are acted upon by no muscles. (See *Operative Surgery*, t. ii. p. 222.) Besides, as Delpech remarks, since the tubes cannot reach the fragments, they cannot support them, and they must be attended with all the inconvenience of foreign bodies placed in contact with parts already inflamed, or about to become so. (*Précis des Mal. Chir.* t. i. p. 222.)

As fractures of the ossa nasi are the result of falls, and direct blows on the face, the soft parts are always either contused or wounded. These fractures are sometimes attended with dangerous symptoms; depending either upon the concussion of the brain, produced by the same blow which causes the fracture; or, on the cribriform lamella and the crista galli of the os ethmoides being driven inwards, so as to compress the brain. This last danger, however, some modern surgeons consider as void of foundation; and whenever the symptoms indicate an affection of the brain, the nature of the case is referred to the intimate connection between the bones of the nose and the os frontis. (*Delpech, Précis des Mal. Chir.* t. i. p. 221, 8vo. Paris, 1816.)

Sometimes the fissure extends through the nasal process of the upper maxillary bone, and across the fossa for the lachrymal sac, and is attended with discharge of blood from the puncta lachrymalia and nostril, and obstruction to the passage of the tears. Mr. Hooper of the London Road had a case in which not only the fissure extended in this way, but the brain received injury from the blow, and the patient died. The accident was produced by a horse-brush being thrown with violence, and striking the face.

When there are symptoms of pressure on the brain (see HEAD, INJURIES OF,) and the ossa nasi are much depressed, the surgeon must immediately raise them, and endeavour to draw gently forwards the perpendicular process of the os ethmoides, which is connected with the cribriform lamella and crista galli. Perhaps a pair of closed common forceps, introduced into each nostril, might best enable the surgeon to do what is necessary. Bleeding and the antiphlogistic treatment may sometimes be required: for the vicinity of the eye renders it liable to become inflamed; and when there are symptoms of injury of the brain, extravasation, &c. the necessity of such practice is still more strongly indicated.

[FRACTURES OF THE ZYGOMATIC ARCH, AND OF THE MALAR, AND SUPERIOR MAXILLARY BONES.]

[The arch of the zygoma may be broken by a blow or a fall on the side of the face, or by a carriage wheel passing over it, but the accident is a rare one, so much so that M. Malgaigne has only been able to collect five examples of it.] The fracture is not in itself serious, and if unattended with much displacement, no particular treatment will be necessary excepting for the accompanying contusion of the soft parts. The fragments may, however, be driven in so as to interfere with the insertion of the temporal muscle into the coronoid process and to interrupt its action, and in that case, if a reduction cannot be effected by pressure with the finger from within the mouth, it might be advisable to make an incision above the zygoma through the integuments and temporal fascia, and to raise the depressed ends of the fracture by an elevator introduced beneath them. This plan has been adopted with success. (See *Malgaigne, Traité des Fractures*, p. 357.)

The malar bones, from their prominent situation at the side of the face, are exposed to similar injuries. They may be driven in and more or less comminuted, or they may be separated from their connexions at the sutures. If there is much displacement, the finger should be introduced into the mouth to replace the broken pieces as nearly as possible in their natural position, and the attempt should be made at an early period after the accident, for they rapidly contract adhesions, and become fixed in their new situation.

The superior maxillary bones are sometimes fractured in such a manner that a portion of the alveolar process is detached from the rest of the bone. In such a case the broken piece must be replaced, and the teeth which it contains must be fixed with ligatures or wire to those belonging to the uninjured portion of the bone. An apparatus fitting on to the teeth, and similar to that recommended for fracture of the inferior maxilla, may also be found useful to retain the detached piece in its proper position.

Other cases occur in which the superior maxillary bones are more severely injured. Mr. South records a remarkable accident in which a man received a violent blow on the face from the handle of a crane whilst flying round. The nose, cheek, and upper jaw bones were broken and crushed, so that the whole face below the eyes, including the floors of the orbits, could be moved with the least effort, and yielded in every way to pressure with the fingers, just as would beans in a bag. This man recovered after having had a little exfoliation from the mouth and nose; but a shallow furrow across the face and a broken nose-bridge were the results of the injury. (See *Chelius' Surgery, translated by South*, vol. i. p. 528.)

M. Malgaigne mentions a case occurring to M. Simonin of Nancy, in which the left side of the face was driven in, and the superior maxillary and palate bones disjoined at their sutures in the median line, and separated from the bones of the opposite side by an interval of nearly half an inch. Notwithstanding other injuries, this patient recovered, with only slight subsequent deformity, and no inconvenience in speech or deglutition.

In all these cases the loose fragments should

never be removed, as they are found to unite with remarkable facility.]

FRACTURES OF THE LOWER JAW.

This bone is sometimes fractured near the chin; but seldom so as to produce a division of the symphysis, the solution of continuity generally happening between this part and the insertion of the masseter. In University College Museum, however, there is a specimen of a fracture situated precisely at the symphysis. In other instances, the fracture occurs near the angles of the jaw, that is to say, between the insertion of the masseter and the root of the coronoid process. The bone may also be broken on each side at the same time; in which event the middle portion is extremely difficult to keep right, because many of the muscles which draw the lower jaw downwards are attached to that part. The condyles and coronoid process are also sometimes broken.

Fractures of the lower jaw may be either perpendicular to its basis, oblique, or longitudinal; of the latter, examples have been known in which a portion of the alveolar process with the teeth in it, was detached from the rest of the bone.

The soft parts are generally contused and wounded. An instance is reported by Dr. Richelot of the accident being complicated with an injury of the facial artery. (*Archives Gén.* Jan. 1833.) J. L. Petit mentions one case in which the bone was broken, and the coronoid process quite denuded, by the kick of a horse.

When the fracture is near the median line, the side on which the symphysis is situated is drawn downward and backward by the sub-maxillary muscles, while the other fragment is supported by the muscles which close the jaw. When the fracture is more backward, the displacement occurs in the same way, but not so easily. When the bone is fractured in two places, the middle portion is always pulled downwards and backwards by the muscles attached to the chin, while the two lateral pieces are kept up by the levator muscles. When the ramus of the jaw is broken, the masseter, being attached to both pieces, prevents any considerable degree of displacement. When the neck of the condyle is fractured, the pterygoideus externus will pull the condyle forwards.

[M. Malgaigne thinks that too much has been attributed to the action of muscles, and that the displacement is often determined by the direction of the blow which occasioned the fracture, and which in most cases operates on one side of the fracture more than on the other. In oblique fractures, also, the direction of the obliquity may determine the direction of the displacement; and he found that in the majority of cases the bone was broken obliquely as regards its thickness, the obliquity passing backwards from the external towards the internal surface. In such a case the posterior piece may project outwards and ride more or less over the larger anterior portion.]

When a blow has been received on the lower jaw, or the bone injured by a fall, or the pressure of some heavy body; when an acute pain is experienced in the part, and an inequality can be felt at the basis of the bone; when some of the teeth, corresponding to that inequality, are lower than the others; and when a crepitus is perceptible on moving the jaw; there can be no doubt of a fracture. When the gums are lacerated, or the bone

denuded by a wound, the case is (if possible) still more manifest.

Fractures of the rami and condyles produce great pain near the ear, particularly when the jaw is moved; and a crepitus may be felt.

Treatment.—Fractures of the lower jaw, whether simple or double, are easily set, by pushing the displaced part upward, and a little forward, and then pressing on the basis of the bone, so as to bring it exactly on a level with the portion which has preserved its natural position. Indeed, the correctness of the reduction may always be rightly judged of by attending to the line which the base of the jaw ought to form, and observing that the arch of the teeth is regular. The maintenance of the reduction, however, is difficult; and can only be well executed by supporting the lower jaw, and keeping it applied to the upper one. As the latter indication cannot be properly fulfilled in persons whose teeth are very irregular, it is sometimes necessary to interpose an even piece of cork between the teeth on each side of the mouth, and against this cork the lower jaw is to be kept up with the bandage presently noticed, while the aperture left between the incisor teeth in the situation where no cork is placed, allows food and medicines to be introduced with a small spoon.

When the bone is fractured in two places, one on each side of the symphysis, and great difficulty is experienced in keeping the central fragment from being drawn downwards and backwards towards the os hyoides by the depression of the lower jaw, the instruments proposed by Graefe, Lonsdale, and others, will fix the bone and prevent the displacement. The apparatus consists of a groove, for the reception of the arch of the teeth, and of a square plate of steel, which is placed under the chin, and admits of being screwed up to the part. On this plate a piece of cork or a compress is put.

[Some surgeons recommend fixing the teeth together with a ligature or a piece of silver or gold wire twisted around them, and this may be of service in maintaining the fractured surfaces in contact, but will not be sufficient unless a bandage or some other apparatus be also employed.]

As soon as the fracture is set the surgeon should adapt some thick pasteboard or gutta-percha, previously wetted and softened, to the outside of the jaw, both along its side and under its basis. Over this moistened pasteboard a bandage with four tails is to be applied, the centre being placed on the patient's chin, while the two posterior tails are to be pinned over the forehead, and the two anterior ones over the occiput. When the pasteboard becomes dry, it forms the most convenient apparatus imaginable for surrounding and supporting the fracture. A piece of soap-plaster may now be applied to the skin underneath, which will prevent any ill effects of the hardness and pressure of the pasteboard.

Until the bone is firmly united, the patient should be allowed only such food as does not require mastication, and it may be given by means of a small spoon, introduced between the teeth. Broths, soups, jellies, tea, and other slops appear most eligible.

In order to keep the middle portion of the bone from being drawn downwards and backwards towards the larynx, it is frequently necessary to apply tolerably thick compresses just under and behind the chin; which are to be well supported

by the bandage already described. I need hardly state the necessity of enjoining the patient to avoid talking, or moving the jaw more than can be avoided. He should also be advised to lie on his back at night, as the pressure of either side of the face upon the pillow will be likely to produce displacement.

[In a case which was under the care of the writer in St. Mary's Hospital, and in which every attempt to remedy the displacement had failed, an apparatus was devised by Mr. H. Hayward, the dentist, which answered the purpose admirably. It consisted of a silver cap made to fit the teeth and gums accurately, and to enclose several teeth on each side of the fracture, a wax cast having been first taken of the parts, and the silver plate having been moulded from it. A piece of gutta-percha was placed under the chin, and was held in its place by being tied on each side with string to two curved bars of silver, which were fixed to the plate inside, and which passed out at the angles of the mouth. By this means the most accurate contact was maintained, and the patient was able to speak and eat without pain and without any risk of disturbing the fracture. The transition from a state of extreme pain and discomfort to one of almost perfect ease as soon as this instrument was applied, was most remarkable. (Further particulars will be found in the *British Med. Journ.* Oct. 9, 1858, p. 845.)]

When the condyle is fractured, as it is incessantly drawn forward by the action of the pterygoideus externus, and, on account of its deep situation, cannot be pressed back, the neck must, if possible, be pushed towards it. For this purpose the bandage must be made to operate particularly on the angle of the jaw, where a thick compress should be placed. [There is some fear, however, notwithstanding every precaution, that the mouth may remain permanently turned toward the injured side.]

Compound fractures of the lower jaw are to be treated on the same principles as similar injuries of other bones. If possible, the external wound should be healed by the first intention; and when this attempt fails, care must be taken to keep the wound clean by changing the dressings about once in three days; but not oftener, lest the fracture suffer too much disturbance. Compound fractures of the jaw, and even simple ones, which are followed by abscesses, are liable to be succeeded by necrosis and exfoliations.

It now and then happens that fractures of the lower jaw continue ununited: Dr. Physick's successful treatment of one such case with a seton, and Dupuytren's by sawing off the end of one fragment, I have already noticed.

Fractures of the coronoid process are stated not to admit of bony union.

FRACTURES OF THE VERTEBRÆ.

On account of the shortness and thickness of these bones, they cannot be broken without considerable violence. The spinous processes, which project backwards, are most exposed to such injury; for they are the weaker parts of the vertebræ, and most superficially situated. On this account, it is possible for them to be broken without any mischief being done to the spinal cord. The violence which is great enough to break the bodies of the vertebræ, must produce more or less concussion,

or other mischief of the spinal cord ; from which more perilous consequences are to be apprehended than from the injury of the bones, abstractedly considered. The displaced pieces of bone may press on the spinal cord, or even wound it, so as to occasion a paralytic affection of all the parts, which derive their nerves from the continuation of it below the fracture.

There may be fractures of the vertebræ without displacement ; or fractures complicated with dislocation, or extravasation of blood on the membranes of the spinal cord, of which last occurrence several specimens are preserved in University College Museum. Sir Benjamin Brodie has noticed that, in consequence of external violence, a narrow clot of blood may be extravasated within the substance of the spinal cord, and that from its peculiar situation it may be productive of the most dangerous symptoms. With respect to laceration of the cord and its membranes, he observes that it may be torn completely through, or lacerated in one part and not in another ; and he refers to a case described by M. Ollivier, in which the attachments of the nerves on one side were destroyed and not on the other.

As for the concussion, the minute organisation of the spinal cord may be injured by it, even when there is neither fracture nor dislocation, and the investing membranes exhibit no effects of the injury. "In such cases, if there be an opportunity of examining the spinal cord at a very early period after the accident, the central part of it is found to be softer than natural, its fibrous appearance being lost in that of a semifluid substance. If the patient survives for a longer period, the alteration of structure is perceptible in the whole diameter of the cord, and occupies from one to two inches, or even more of its length ; and at a still later period, it has often proceeded so far as to terminate in its complete dissolution." (*Sir B. Brodie in Med. Chir. Trans.* vol. xx. p. 121, 122.)

Sir Astley Cooper divides fractures of the bodies of the vertebræ with displacement into two classes : first, those which occur above the third cervical vertebra ; and, secondly, others which happen below that bone. The first cases, he says, are almost always *immediately* fatal, if the displacement be to the usual extent. In the second description of cases, death takes place at various periods after the injury. The reason of this difference is ascribed to the circumstance of the phrenic nerve originating from the third and fourth cervical pairs, whence in the first class of cases death is immediately produced by paralysis of the diaphragm, and the stoppage of respiration. (*On Dislocations*, p. 552.)

Sir Benjamin Brodie correctly refers the symptoms which arise as an immediate consequence of injuries of the spine ; 1st, To concussion of the spinal cord ; 2nd, To laceration, or division of its substance ; 3rd, To pressure made on it, either by displacement of bone, or by extravasated blood. Afterwards inflammation of the membranes of the cord may take place, and other organs may be secondarily affected, giving rise to another order of symptoms which did not exist in the beginning. He adds that, when the symptoms are viewed generally, they vary : 1st, according to the part of the spinal cord on which the injury has been inflicted ; 2nd, according to the kind and degree of injury which the cord has sustained ; 3rd, according as, from accidental circumstances, the

life of the patient is prolonged for a longer or shorter period, or ultimately preserved. (*See Brodie in Med. Chir. Trans.* vol. xx. p. 127.) These facts deserve to be particularly remembered, for without the recollection of them the practitioner would be extremely perplexed in his endeavours to explain the great differences in the symptoms and results of different cases.

As the mere concussion of the spine may occasion symptoms which resemble those usually occurring when the vertebræ are fractured, the diagnosis is generally obscure. An inequality in the line of the spinous processes, and a crepitus, may sometimes be distinctly felt. The lower extremities, and the rectum and bladder, are generally paralytic ; the patient being afflicted with retention of urine and involuntary discharge of the fæces.

According to Sir Benjamin Brodie's observations, the patient is generally unconscious of the bladder being distended ; but occasionally he suffers as from an ordinary retention of urine, though in a less degree. "The incapability of voiding the urine is usually an early symptom, and in fatal cases it continues to the last. When a complete or partial recovery takes place, the power of emptying the bladder is restored sooner than that of using the muscles of the lower limbs. In cases in which the catheter is not employed, the urine flows involuntarily, as in most other cases of over-distended bladder where the urethra is free." "At other times there is a constant dribbling of urine, although the bladder is in a contracted state, so that, on the introduction of the catheter, no urine flows." (*Sir B. Brodie, in Med. Chir. Trans.* vol. xx. p. 141.)

With respect to *paralysis of the voluntary muscles*, Sir Benjamin Brodie remarks, that, if the spinal cord be divided through its whole substance, or extensively lacerated, or subjected to any considerable pressure, the paralysis is immediate and complete. But if the injury be partial, certain muscles may be paralysed, while others retain their power of voluntary motion. He notices also the well-known fact, that paralysis of the lower limbs is more common than that of the upper. "In some cases, in which the injury has affected the spinal cord in the lower part of the neck, the lower limbs are rendered paralytic, while there is either no paralysis, or a less degree of it, in the upper limbs. The reason of this is sufficiently obvious to any one who considers what are the origins of the nerves which form the axillary plexus, some of them being probably above the part which is injured. But the circumstance is still remarkable in this respect, that it is contrary to what happens, when the functions of the spinal cord are interrupted in consequence of caries of the cervical vertebræ. In these last cases the paralysis is often complete in the upper limbs for many weeks, or even for months, before it extends to the lower. I have met with only a single case in which, after an injury of the cervical portion of the spine, there was almost complete paralysis of the muscles of the upper extremities, and none whatever of those of the lower." (*Sir B. Brodie, in Med. Chir. Trans.* vol. xx. p. 129.) I think we must agree with the same experienced surgeon that, when paralysis of the upper and lower limbs follows a fracture of the lumbar vertebræ, an instance of which is recorded by Mr. Stafford, or when it follows a concussion of the loins, as once

seen by Sir Benjamin Brodie himself, we must suppose, that another part of the spinal cord, as high as the origin of the nerves which form the axillary plexus, has suffered from the effects of concussion.

On the subject of *affections of the nerves of sensation*, Sir Benjamin Brodie, after noticing the well ascertained fact, that if the spinal cord be lacerated, or subjected to any considerable degree of pressure, the sensibility of the parts below the seat of injury is totally destroyed, refers to another, which is, that, if the injury be in the situation of the sixth or seventh cervical vertebra, the destruction of sensibility is frequently partial in the upper extremities, while it is complete in the trunk and lower extremities. "In many instances, the destruction of sensibility is incomplete at first, but becomes complete afterwards, as the process of softening makes progress in the injured portion of the spinal cord." (*Sir B. Brodie in Med. Chir. Trans.* vol. xx. p. 135.)

With respect to the *affection of respiration*, if the fracture be as high as the third cervical vertebra, and the cord be there injured, the nervous influence cannot be transmitted either to the diaphragm or the other muscles of respiration; and a fatal asphyxia immediately takes place. But if respiration be performed artificially by inflating the lungs, the action of the heart and life may be maintained for several hours. When the spinal cord is seriously injured in the lower part of the neck, below the origin of the phrenic nerves, or in the upper part of the back, the action of the diaphragm is not interfered with, while the intercostal muscles, as well as the muscles of expiration, are paralytic. "The patient, therefore, breathes by the diaphragm only. The ribs are motionless, and the air is expelled from the lungs, not by the contraction of the abdominal muscles, but simply by the elasticity of the abdominal parietes, and the pressure of the abdominal viscera, operating on the lower surface of the diaphragm, when that muscle is relaxed." Under these circumstances, the patient is incapable of expectorating mucus, if it be collected in the trachea; if he coughs, it is by a forcible inspiration, followed by a sudden relaxation of the diaphragm; and respiration is carried on with more difficulty in the sitting than the recumbent posture. But it is further observed by Sir Benjamin Brodie that injuries of the spinal cord in the lower part of the neck are not necessarily followed by the foregoing consequences. The pressure on the spinal cord may be so small, or the disorganisation of it from concussion may be so trifling, that the muscles of respiration are not at any period affected by it; or they may not be so in the first instance, and yet become affected afterwards. In one case, which fell under Sir Benjamin Brodie's observation, a fracture of the seventh cervical vertebra, which was followed by a softening and dissolution of the spinal cord, the difficulty of respiration did not take place until the twelfth day; but death occurred in less than three days afterwards. (*See Med. Chir. Trans.* vol. xx. p. 138.)

Injuries of the spinal marrow, including those resulting from, or accompanying fracture, are well known to produce certain *changes in the urine and urinary organs*. Besides an inability of voiding the urine, there is sometimes, as Sir Benjamin Brodie has pointed out, a marked diminution in

the quantity of this fluid secreted. In some cases, the urine first secreted, although of an acid quality and free from mucus, has a peculiarly offensive smell; while, in others, it is exceedingly acid, with an opaque yellow appearance, and a yellow amorphous sediment. But the most common changes are an ammoniacal smell, great turbidness, and a deposit of a large quantity of adhesive mucus, and the urine, when tested with reddened litmus, or turmeric paper, is found to be very alkaline. After some time, phosphate of lime, secreted by the inner coat of the bladder, is blended with the mucus, which is tinged with blood. These appearances may come on as early as the third or fourth day, or not begin for a week, or eight or nine days. Sir Benjamin Brodie has not found that injury of one part of the spine is more liable to produce them than that of another. In fatal cases they sometimes continue to the last. At other times they go on for two or three weeks, and then subside. Occasionally the urine varies from day to day, being now alkaline and depositing adhesive matter; then clear and acid; and afterwards alkaline again. (*Sir B. Brodie.*)

Fractures and other injuries of the spine frequently bring on inflammation of the mucous membrane of the bladder and ureters; and occasionally spots of extravasated blood are found in the kidneys. In University College Museum is a bladder, taken from a patient who died of an injury of the spine, which is in a softened and ulcerated state. In Mr. Barlow's case the infundibula and pelvis of the kidneys were dilated with urine, which was mixed with pus. The bladder, whose coats were thickened, also contained a considerable quantity of pus. (*See Med. Chir. Trans.* vol. xvii. p. 120.)

Wherever the injury of the spinal cord is situated, the bowels are torpid, and the abdomen tympanitic. In many cases where the cervical portion of the cord is injured, and the patient dies in two or three days, there is a disposition to vomit. In more protracted cases the discharges from the bowels are of a black colour, semifluid, and of a peculiarly offensive smell. It would appear also, both from the experiments of M. Chossat, and facts recorded by Sir Benjamin Brodie, that injuries of the superior portion of the spinal cord are sometimes followed by a remarkable evolution of animal heat. (*See Med. Chir. Trans.* vol. xx. p. 146.)

With respect to effects on the sensorium immediately after the accident, Sir B. Brodie has not observed any material ones, except where the injury was of the cervical portion of the spinal cord, and then he observes that the results are very different in different cases. (*Ib.* 149.)

If the lumbar vertebræ are displaced, the lower extremities are rendered so completely insensible, that they may be pinched, burnt, or blistered, without the patient suffering any pain. The penis in such cases is generally erect. In general, also, according to Sir Astley Cooper's observations, patients with fractured lumbar vertebræ die within a month or six weeks; but he knew of one patient that lived two years, and then died of gangrene of the nates. In fractures with displacement of the dorsal vertebræ the symptoms are very similar; but the paralysis extends higher, and the abdomen becomes excessively inflated. Death commonly follows in two or three weeks; but Sir Astley Cooper remembers one case in which a gentleman

survived the accident nine months. According to Sir B. Brodie's experience, where a considerable injury has been inflicted on the spinal cord in the lower part of the neck, or in the neighbouring part of the back, of such a nature as to paralyse all the muscles of respiration excepting the diaphragm, the patient rarely lives to the end of the fourth or fifth day, and mostly dies still earlier. (See *Med. Chir. Trans.* vol. xx. p. 156.) Fractures of the cervical vertebræ below the origin of the phrenic nerve occasion paralysis of the arms, though it is seldom complete. Sometimes, when the fracture is oblique, one arm is more affected than the other. As the intercostal muscles are paralytic, great difficulty of respiration prevails. The abdomen is also considerably inflated. Death generally follows in from three to seven days.

Sir Benjamin Brodie has never known priapism occur from injury of the spinal cord, except in combination with paralysis. It "may take place (he observes) whether the patient suffers from the effects of simple concussion of the spinal cord, or from those of pressure. It seems to be connected with injuries of the upper, rather than with those of the lower portion of the cord, at least I am not aware that I have met with it where the seat of injury has been below the sixth dorsal vertebra. It is for the most part an early symptom, showing itself in the course of the second or third day, and it seldom continues after the first fortnight. It occurs even where the sensibility of the parts is totally destroyed, and may be induced by the mechanical irritation caused by the introduction of the catheter, where the patient is entirely unconscious of the operation. This circumstance was pointed out to me, many years ago, by Professor Macartney, of Trinity College, Dublin, and I have had many opportunities of verifying the correctness of the observation." (*Sir B. Brodie*, in *Med. Chir. Trans.* vol. xx. p. 140.) In University College Hospital, one case occurred under Mr. Liston, in which priapism accompanied a fracture of the lumbar vertebræ, and Sir Benjamin Brodie informs me that he has lately heard of another similar case. We had also in University College Hospital an instance where priapism was one of the symptoms following a violent blow on the occiput.

Sir Astley Cooper notices the following as the appearances found in *post-mortem* examinations. The spinous process of the displaced vertebra is depressed; the articular processes are fractured; the body of the vertebra is broken through, the separation rarely happening in the intervertebral substance. The body of the vertebra usually projects forward half an inch, or an inch. Between the vertebra and the sheath of the spinal marrow, blood is extravasated, and frequently on the spinal cord itself. When the displacement is slight, the spinal marrow is compressed and bruised. When greater, it is torn through by the bony arch of the spinous process, and a bulb is formed at each end, but the dura mater continues whole. (See *Sir A. Cooper*, *On Dislocations, &c.* p. 554, &c.)

Fractures of the spinous processes, without other serious mischief, are not dangerous. It has usually been thought that, even when a fracture of the spine is attended with displacement, any attempt to bring the fragments into a better position would be too dangerous to be made. Some practitioners have however ventured upon it. Mr. Barlow,

of Writtle, did so, and though no harm resulted from the experiment, it cannot be said that any permanent good was derived from it, for, when the patient died some months afterwards, the fracture had united still in a displaced condition. It was "performed by persons pulling at the superior and inferior extremities, which had the desired effect; for the angular projection was greatly lessened, and the patient did not seem to experience any pain during the extension." The following particulars show, however, that the displacement was far from being obviated. The case was a transverse fracture of the first lumbar vertebra, extending obliquely downwards and forwards, through the upper portion of its body. "The upper part of the vertebral column, together with the upper fragment of the fractured vertebra, had been thrown forwards, the superior fragment resting on the fore and upper part of the inferior fragment, to which it was connected by callus. The corresponding articular process of the last dorsal and first lumbar vertebræ had been dislocated; those of the former having been thrown upwards and forwards. On the right side the inferior articular processes of the last dorsal vertebra was separated from the corresponding process of the first lumbar to the extent of a third of an inch, while their surfaces were rounded and nearly obliterated. On the left side the processes were about the same distance from each other, but connected by an intermediate portion of new bone. The foramen between the roots of the spinous processes was more than twice its natural dimensions. The ligamenta subflava must have been ruptured. The vertebral canal, immediately behind the line of fracture, was diminished one half in calibre." (*W. R. Barlow*, in *Med. Chir. Trans.* vol. xvii. p. 115.)

The following is the view adopted by one high authority: "Dislocations and fractures, with displacement of the cervical vertebræ, are not always immediately fatal; and I cannot say that no circumstances can exist which would justify the attempt to effect reduction in such cases; but it is evident that if the attempt be made at all, it must be with the greatest caution, and Boyer describes a case in which a child died under it. There can be no doubt, however, that when the injury is in the lower part of the spine, the attempt to effect reduction may be not only made with impunity, but that it may be successful. In proof of this assertion, I may refer to a case which occurred in the practice of Mr. Hardwicke, of Epsom; the patient being afterwards admitted into St. George's Hospital, labouring under paralysis of the lower limbs." Sir Benjamin Brodie likewise refers to another case under his care in the same hospital; a fracture, with great displacement of the third and fourth lumbar vertebræ. By fixing the thorax, and cautiously extending the pelvis, he endeavoured to restore the vertebræ to their proper place. "The attempt was in some degree successful, no ill effects of any kind resulted from it." (See *Med. Chir. Trans.* vol. xx. p. 158.)

In the instances seen by Mr. Crosse, in which a fracture of the spinal column was attended with displacement, producing pressure on the medulla and paraplegia, the compressing portion of the bone was almost universally the body of a vertebra, so generally broken, and not the arch. (See *Trans. of Prov. Med. Assoc.* vol. v.)

[M. Malgaigne mentions a case of fracture in the

lumbar region with projection backwards of the spinous process and paralysis, in which he endeavoured to remedy the displacement which was presumed to exist, by fixing the upper part of the body on an inclined plane and raising the lumbar region by cushions placed beneath it, so as to employ at the same time direct extension and pressure. The attempt appears to have succeeded, for the paralysis shortly disappeared and the patient recovered. (See *Traité des Fractures*, &c. t. i. p. 423.)

Mr. Tuson has also recorded two cases successfully treated in the Middlesex Hospital by extension. In the first there was irregularity and displacement of the last cervical and first dorsal vertebræ, with complete paralysis and priapism. "Upon extension being steadily used, by the head being fixed, and the legs gradually and progressively pulled, complete power of motion and sensation all at once returned as usual. He said he was quite right, and pulled up both his legs and kicked them about in every direction. The priapism soon ceased." He suffered from numbness in the arms and legs, and also from pain at the back of his neck, but was able to leave the hospital at the end of three weeks, and in another month is said to have been perfectly well.

In the second case, a depression was felt in the situation of one of the cervical vertebræ, with indistinct crepitus, but the history is not so satisfactory, as the man was insensible when admitted. Extension was made as in the last case, and during its use the breathing, which had previously been difficult, rapidly improved. Fourteen ounces of blood were taken from the arm, and he shortly became sensible and began to move himself about. Sensation, however, did not return for some hours afterwards. In two days this man was able to leave the hospital and go to his business. (See *Medical Times*, vol. x. 1844, p. 381.)

If, after a certain time, circumstances justify the suspicion of inflammation of the spinal cord, and the state of the pulse will admit of the practice, venesection should be employed; but, inasmuch as cupping the part near the injury could not be performed without turning the patient, and disturbing the fracture, I deem it always inadvisable. The same remark applies to leeches. I believe with Sir Benjamin Brodie, however, that it is a great mistake to suppose that bleeding is always proper. "In the majority of cases, the state of the pulse is such as actually to contra-indicate the abstraction of blood; and the blood, when drawn, does not in general present those appearances which are supposed to mark the existence of inflammation." (Sir B. Brodie, in *Med. Chir. Trans.* vol. xx. p. 162.) Neither does blood-letting seem to this gentleman to arrest the process of softening and dissolution of the spinal cord, but, on the contrary, to accelerate it.

Keeping the vertebral column perfectly motionless is an indication plainly presenting itself, and the best mode of fulfilling it is to let the patient lie steadily on his back.

When the patient is affected with a flatulent distension of the abdomen, vomiting, hiccough, &c. the belly may be rubbed with camphorated liniment: and purgative or turpentine clysters and antispasmodics given.

In all cases in which the lower part of the body is paralytic the catheter is necessary. "It does

not, however, prevent the urine becoming alkaline, nor the secretion of adhesive mucus from the lining membrane of the bladder. When these changes have taken place, the bladder should be emptied several times daily; and it may be advisable in some instances to inject tepid water into it, so as to prevent any portion of the mucus being retained in its cavity." (Sir B. Brodie.)

The torpid state of the bowels demands active purgatives, as calomel, jalap, castor and croton oil. Sir B. Brodie finds that the action of purgatives, in these cases, is promoted by combining them with ammonia. When the motions are black and offensive, attention to this part of the treatment is of high importance. (Op. et vol. cit. p. 163.)

When the bladder, rectum, and lower extremities are paralytic, Boyer advised rubbing the back, loins, sacrum, and limbs with liniments containing the tincture of cantharides. With respect to the external and internal use of stimulants, however, it can never be judicious, when there is reason to apprehend much inflammation of the injured parts; and as for the idea of thus restoring the nervous influence, there can be little chance of success, the cause of its interruption being here of a mechanical nature. (*Delpech, Mal. Chir.* t. i. p. 222.) In an early stage of the case, who would venture to move the patient about for any purpose of this kind?

Some authors recommend trepanning, or cutting out a portion of the fractured bone, when the compression of the spinal marrow, or its injury by a splinter, is suspected; but, according to my judgment, the indication can never be sufficiently clear to authorise the operation, which, on account of the great depth of the intervening soft parts, must be tedious, and even difficult to effect, without risk of increasing the injury, which the spinal marrow may already have received. An unsuccessful operation of this kind was once performed by Mr. H. Cline, and another by Mr. Tyrrell.

Some cases, published by Sir C. Bell, tend to prove, that the danger to be apprehended from injuries of the vertebræ is the same as that which accompanies injuries of the brain. Hence, he is an advocate for general and local bleeding, and keeping the patient perfectly quiet. But, with respect to operations for the removal of fragments of bone, it is his decided belief, that an incision through the skin and muscles covering the spine, and the withdrawing of a portion of the circle of bone, which surrounds the marrow, would be inevitably fatal, the membranes of that part being particularly susceptible of inflammation and suppuration. And, even if a sharp spiculum of fractured bone had run into the spinal marrow, and caused palsy of the lower parts of the body, Sir C. Bell thinks, that exposing the medulla to extract the fragment would so aggravate the mischief, that inflammation, suppuration, and death, would be the inevitable consequences. (*Surgical Obs.* vol. i. p. 157.)

The question, respecting such an operation, seems to Sir Benjamin Brodie to lie in a very small compass. "If the whole, or nearly the whole, of a vertebra be driven forwards, the depression of the posterior part of it will, of course, occasion a diminution of the size of the spinal canal; but the removal of any portion of the vertebra, which is accessible to an operation, will be

of little avail, as the irregularity in the anterior part of the canal, made by the displacement of the body of the vertebra, must be the same after, as it was before, the operation." This view coincides with that which I have long entertained. (See *First Lines of Surgery*, ed. vi. p. 586.) "If (observes Sir Benjamin Brodie) there be simply a fracture on each side of the spinous process, with a depression of the loose or intermediate portion of bone, there must be a corresponding diminution of the size of the vertebral canal; but, as that canal is much larger than the spinal cord, which it contains, it does not follow that the spinal cord is really compressed, or that any material diminution of the symptoms would follow the elevation or the depression. But let it be supposed that the spinal cord is really suffering from pressure, a much less degree of violence than that which is necessary to occasion a fracture of the spine may produce concussion, softening, and ultimately dissolution of the spinal cord, with a train of symptoms much worse than those which arise from simple pressure. Now, no operation can be of the smallest advantage in this respect; but, on the contrary, if it be necessary to apply the saw in the performance of it, the jar and disturbance of the parts, which it must occasion is even likely to aggravate the mischief. If these views be correct, it is evident that the cases, in which there are any reasonable grounds for the performance of the operation, must be of very rare occurrence." (Sir B. Brodie, in *Med. Chir. Trans.* vol. xx. p. 160.) In fact, no operation of this kind has yet been the means of preserving life, or even of relieving the worst symptoms.

Sir Charles Bell describes inflammation of the spinal marrow as "attended with an almost universal nervous irritation, which is presently followed by excitement of the brain: in the meantime, matter is poured into the sheath of the spinal marrow, and either by its pressure causing palsy, or by its irritation disturbing the functions of the part, so as to be attended with the same consequences. The excitement of the brain being followed by effusion, death ensues" (p. 159). Cases are also referred to where palsy of the lower extremities comes on several months after an injury of the spine, owing to thickening of the membrane of the medulla, or disease of the latter part itself. Here Sir C. Bell recommends perseverance in local bleeding and deep issues (p. 160).

When recovery takes place, the restoration of sensibility usually precedes that of the power of voluntary motion. The power of emptying the bladder is also sooner restored than that of using the muscles of the lower limbs. (Sir B. Brodie, op. et vol. cit. p. 136—141.)

A fracture of the processus dentatus almost always proves instantly fatal, as happened in the example mentioned by Sir A. Cooper. (*On Dislocations, &c.* p. 548.) In the article DISLOCATION, I have adverted to the remarkable instance of a fracture and displacement of the atlas, where the patient lived forty-seven weeks after the accident, and to the last week of his life was able to walk to the water-closet, which was on the same floor with his bed. After death "the condyles of the occiput still rested upon the articulating surfaces of the atlas, but the atlas was found to be not a separate and independent vertebra, but an appendix to the axis. So much of its anterior portion as

includes the surfaces by which it is articulated with the occiput and with the axis, had been violently separated from the posterior portion of its ring, and had been carried in an oblique direction downwards and forwards, until it arrived upon the same plane, but anterior to the axis, to the body and transverse processes of which it became attached by perfect bony union, while the posterior fragment had suffered no displacement. Under these circumstances, the bone presented two spinal foramina, and four transverse, but no odontoid process. This organ having been fractured and separated, no organ passed through the anterior spinal foramen." (B. Phillips, in *Med. Chir. Trans.* vol. xx. p. 82.) In the practice of Mr. Cline, a case occurred in which a boy, with a fracture of the atlas, lived a year after the accident.

The particulars of the following case, under my care in University College Hospital, were registered by Mr. Morton, then house surgeon:—Thomas Robinson was admitted November 2, 1835, for injuries received by the fall of a very heavy piece of timber on the lower part of the neck, a short time before he was brought to the hospital. He was perfectly sensible; the pupils were quite active under the influence of light, and no symptom prevailed indicating affection of the brain. His arms and superior extremities were completely paralysed. If raised up, and the support then removed, they immediately dropped. The man had lost all sensation in the inferior extremities and in the trunk, as high as the middle of the chest; also in the arms, excepting from the point of the shoulder down to the elbow. He had *priapism*, with *emissio seminis*. Respiration was performed imperfectly, and in a short hurried manner. Though pain was experienced in the back of the neck when the head was moved, no crepitus was distinguishable. In respiration, no action of the intercostal and abdominal muscles could be perceived. The next day, as no urine had passed, a pint was drawn off with a catheter; and gr. viij. of calomel, followed by aperient mixture, were given to promote evacuations from the bowels. The mixture was rejected by vomiting. In the afternoon the pulse had risen to 120 beats in a minute, and the difficulty of breathing had increased. The face was flushed, and skin hot. Twenty-four ounces of blood were taken away; but without benefit, as the pulse afterwards rose to 156, and became irregular both as to rhythm and strength. Death took place twenty-four hours after the accident. In the *post mortem* examination, the right articular process was found detached from the body of the third vertebra. The left portion of the arch of the fourth was broken, but not displaced. The arch of the fifth was much comminuted, and the spinal cord exposed and pressed upon. The body of this vertebra was also broken through, and the sharp edge of the fracture had caused copious extravasation behind the pharynx, in front of the vertebral column.

William Parker, æt. 13, was admitted under me, October 15, 1836, in consequence of his cravat having been caught by some machinery, and his neck drawn against a projecting lever. In this position he had been suspended about a minute and a half, and directly he had been released he was brought to the hospital. His breathing was then slow, and somewhat laboured, the face slightly livid, the pupils acted, the hands were warm, and

the pulse rather slow and feeble. In eight or ten minutes the lips became livid, the pulse sunk, and the surface of the limbs and trunk began to grow cold. Hot water was applied to the feet, the chest, and epigastrium, and artificial respiration was resorted to by closing the nostrils, and blowing air into the mouth through a piece of muslin. This soon brought a rosy colour into the cheeks, the pulse became stronger, the temperature of the body rose, and some slight effort at respiration was supposed to be made. Whenever the artificial respiration was discontinued, the breathing went on but slowly and feebly, the pulse sunk, and the lips became livid. In this manner he went on for some hours, the vital powers partially recovering, while artificial respiration was carried on, and sinking directly it was interrupted. Although there was great suspicion entertained that the spine had suffered injury, I wished to render the introduction of air into the lungs as complete as possible, and therefore performed tracheotomy, so that a small pair of bellows might be used for this purpose. But neither this plan, nor galvanism, tried by Dr. Ritchie, was of any material service; and death took place at the end of six hours and a half. In the *post mortem* examination, blood was found effused between the muscles in front of the cervical vertebræ. The anterior common ligament was ruptured opposite the second and third vertebræ. A considerable quantity of blood was found in the intermuscular cellular tissue behind the cervical vertebræ, opposite the second, third, and fourth of them. A fracture of the arch of the third was detected, the part of it above the spinous process being broken off, and the portion of it on each side of that process also fractured. Although the fragment might have been depressed, it did not seem to be so at the period of examination. In the spinal canal blood was effused; but there was no apparent laceration of the dura mater, or injury of the cord: the bowels were greatly distended with air. This case, which I have also referred to in the article ASPHYXIA, illustrates the consequences of an injury of the spinal cord, implicating the origins of the phrenic nerves.

FRACTURES OF THE STERNUM.

The sternum is less frequently broken than its exposed position might lead us to expect; and the reason of this fact is imputed to the bone resting, as it were, upon the yielding cartilages of the ribs, and also, in some measure, to its spongy texture. When the accident does occur, it is in most cases from the direct application of external violence to the injured part; and then the fracture is always accompanied with contusion, or even a wound of the integuments, and more or less injury of the thoracic viscera.

[Its direction is generally transverse or slightly oblique, and when there is displacement, it is found that most commonly the upper piece is de-

pressed backwards towards the thorax. More rarely, the fracture has been found to take a vertical direction, so as to separate the bone into two lateral halves.]

As Boyer remarks, the sternum, in consequence of the elasticity of the cartilages of the ribs, may be readily propelled backward by pressure in this direction, and the result is an actual change in the form, and a real diminution of the chest. Now, since this cavity is always accurately filled by its contents, these alterations cannot happen in a considerable and sudden manner, without a risk of the thoracic viscera being contused and even ruptured. Thus, when the sternum has been fractured by violent blows on the chest, the heart and lungs have been found severely contused, and sometimes lacerated; and there will always be greater danger of such mischief, when the fracture is attended with depression of one or more of the fragments. In the Museum of University College is a heart, the right ventricle of which was lacerated by the fragment of a broken sternum. M. Sanson saw a similar occurrence. (See *Dict. de Méd. et de Chir. Pratiques*, art. *Fracture*.) In some cases, a large quantity of blood is effused in the cellular tissue of the anterior mediastinum; and in others, the accident is followed by inflammation and suppuration in the same situation, and necrosis of the broken part of the bone. Since the lungs are also liable to be ruptured by the same force which causes the fracture, or wounded by the depressed pieces of bone, emphysema may be another complication, as was exemplified in a case related by Flajani. (*Collezione d'Osservaz. &c. di Chir.* t. ii. p. 214. 8vo. Roma, 1802.)

[The sternum has been known to be fractured without direct violence either from the contre-coup occasioned by falls on the back or other parts of the body, or as some have supposed, by the violent action of the muscles connected with it. Chaussier saw two fractures from muscular action in the efforts of parturition. In both these cases the trunk and head were strongly bent backwards at the moment of fracture. (See *Malgaigne, Traité des Fractures*, &c. t. i. p. 451.)]

A fracture of the sternum is rendered obvious by the inequalities perceptible, when the surface of the bone is examined with the fingers; by a depression, or elevation of the broken pieces; a crepitus and an unusual movableness of the injured part in respiration. The breathing is difficult, and mostly accompanied with cough, spitting of blood, palpitations, and inability to lie on the back. According to the observations of Petit and Baldinger, several of these latter symptoms may continue, with less intensity, a long while after the fracture has been cured. (*Leveillé, Nouvelle Doctrine Chir.* t. ii. p. 243.) When displacement occurs, the lower fragment generally is pushed forwards, or even more or less overlaps the upper.

Fractures of the sternum, when they are mere solutions of continuity, only require common treatment; viz. a bandage round the chest, quietude, and a low regimen, with the view of preventing what may be considered as the most dangerous consequence, inflammation within the chest.

In cases attended with great depression of the fractured bone, the necessary incisions should be made, in order to raise with an elevator the portions of the bone driven inwards, or to extract with forceps any loose splinters, which seem to be simi-

larly circumstanced. However, it is not often necessary to trephine the sternum, either to raise a depressed portion of the bone, or to discharge extravasated fluid. In the first circumstance, I believe with Sir C. Bell, that the formal application of the trephine can never be right, though the surgeon may be called upon to extract loose splinters. (See *Operative Surgery*, vol. ii. p. 218.) Such an operation, however, may occasionally be proper when abscesses form under the sternum, or the bone is affected with necrosis, and the natural separation of the diseased parts is likely to occupy a considerable time.

Fractures of the sternum are more frequently produced by gunshot violence, than by any other cause, and in these cases the splinters may require extraction. At the battle of Marengo, the French general Champeux received such a wound, with which he lived nearly a month: the injury was attended with so many splinters, that when they were removed, the pulsations of the heart were visible to a considerable extent. (*Leveillé*, vol. cit. p. 214.)

The ensiform cartilage, when ossified in old subjects, is liable to fracture. Little more can be done in such a case than to relax the abdominal muscles by raising the thorax and pelvis, and then apply a bandage to the part, for the purpose of keeping it steady.

FRACTURES OF THE RIBS.

Several of these bones are often broken together, but the first rib being protected by the clavicle, and the lower ribs being very movable, are less liable to fracture than the others.

[Fractures of the ribs may be caused either by direct violence, such as a blow or fall, in which case the fracture takes place at the point where the force is applied, and the broken ends are driven *inwards*; or by compression of the thorax, when they generally give way at the most convex point, and the fractured ends project *outwards*. Thus, if the pressure be applied in the antero-posterior direction, the fracture will most likely occur somewhere near the centre of the bones, and if it operate laterally, they will, in all probability, be broken in the neighbourhood of their angles.

The ribs have also been known to be broken by muscular action in the efforts of coughing. Of this singular accident, the possibility of which has been called in question, M. Malgaigne has collected seven recorded examples. (See *Traité des Fractures*, p. 429.)]

The case first mentioned is the most serious, for when the spicula of a fractured rib are beaten inward, they may lacerate the pleura, wound the lungs, and cause the dangerous train of symptoms attendant on emphysema. (See EMPHYSEMA.) The pointed extremity of the rib, projecting inwards, may cause an extravasation of blood; or, by its irritation, produce inflammation in the chest. A fracture, not at all displaced, or situated under thick masses of muscles, may be difficult to detect, particularly in fat subjects; and, no doubt, is frequently never discovered. The surgeon should place his hand on the part where the patient seems to experience a pricking pain in the motions of respiration, or where the violence has been applied. The patient should then be requested to cough, in which action the ribs must necessarily undergo a sudden motion, by

which a crepitus will often be rendered perceptible. All the best practitioners, however, are in the habit of adopting the same treatment, when there is reason to suspect a rib to be fractured, as if this were actually known to be the case by the occurrence of a crepitus or the projection of one end of the fracture; which, indeed, in the instances which are displaced, makes the nature of the accident sufficiently plain.

A broken rib cannot be displaced either in the direction of the diameter of the bone, or in that of its length. The ribs being fixed posteriorly to the spine, and anteriorly to the sternum, cannot become shortened. Nor can one of the broken pieces become higher or lower than the other, because the same muscles are attached to both fragments, and keep them at an equal distance from the neighbouring ribs. The only possible displacement is either outward or inward. In the treatment of simple fractures of the ribs, free from urgent symptoms, the principal indication is to keep the broken bones as motionless as possible. For this purpose, a broad linen roller is to be firmly put round the chest, so as to impede the motion of the ribs, and compel the patient to perform respiration chiefly by the ascent and descent of the diaphragm. A scapulary will prevent the bandage from slipping downwards. As a roller is apt to become slack, many surgeons, with good reason, prefer a piece of strong linen, large enough to surround the chest, and laced with packthread, so as to compress the ribs in the due degree.

[Mr. Hilton recommends strapping the chest in such a manner as to prevent the movements of the ribs on the injured side only. For this purpose, he applies strips of adhesive plaster circularly (round the injured side) from the spine to a little beyond the sternum, thus leaving the opposite side of the chest free for the purposes of respiration, and also not impeding in any way the movements of the abdomen. He states that he has found this method give great relief in cases where the patient could not bear the usual bandage, which not unfrequently happens. (See *Lancet*, vol. i. 1852, p. 255.) This method has been frequently practised by the writer, who has found it produce almost perfect ease, where a bandage including the whole chest only aggravated the distress.

Sometimes compression of the chest is not desirable; for instance, where the ribs are broken in several places, or where they are much driven inwards, it would often only aggravate the mischief. Fortunately in all cases the surgeon has a safe guide in the sensations of the patient, and if the bandage increases the distress, he may be sure that it is doing mischief, and should immediately remove it.

If the broken rib has penetrated the lung, the circumstance is made known by the more severe dyspnoea, the expectoration of blood, and probably, emphysema of the subcutaneous areolar tissue in the neighbourhood of the fracture. This latter symptom may be considered as positive proof of the nature of the injury, as it can only be occasioned by the passage of the rib through both layers of the pleura into the substance of the lung. (See EMPHYSEMA.)]

When, therefore, there is reason from these symptoms to think the lungs injured, or disposed to inflame, copious and repeated bleedings should be practised; and as pleuritis or pneumonia is always liable to succeed such an accident, and is a most dangerous occurrence, the greatest possible

vigilance is called for on the part of the surgeon: for the treatment, to be effectual, should be employed at the earliest period of the accession of the inflammatory symptoms.

Calomel in repeated doses, combined with antimony, should also be administered, and the *mistura cetacei*, with opium, will be found an excellent medicine for appeasing the cough, which disturbs the fracture, and gives the patient infinite pain.

[The patient should be kept perfectly quiet, with his head and shoulders raised, and should only take food of the mildest possible character.]

FRACTURES OF THE CLAVICLE.

This bone being long and slender, unsupported at its middle, and protected externally only by the integuments, is very often broken.

Its serving to keep the scapula at a proper distance from the sternum, and as a point of support for the *os brachii*, every impulse of which it receives, fully accounts for the fact.

The most frequent cause is a fall on the point of the shoulder, or on the elbow or hand, when the arm is separated from the side.

In fracture from this cause, the middle of the bone, where the curvature is greatest, is most frequently the situation of the injury. It is not very often fractured at its scapular, and still more rarely near its sternal extremity.

When the fracturing force is applied to the ends of the bone, as in a fall on the point of the shoulder, or on the hands, while the arms are extended, the clavicle may be bent, and fractured so obliquely, that the broken portions protrude through the skin.

Less frequently, the fracture is caused by direct violence, in which case the bone will be broken at the point on which the force immediately acts, and then the soft parts will be contused, or even lacerated.

A comminuted fracture may be thus occasioned, and if the violence be very great, the axillary nerves may be injured. Mr. Earle mentions an instance, in which the axillary plexus of nerves was crushed by a comminuted fracture of the clavicle, and paralysis of the arm occasioned. (See *Med. Chir. Trans.* vol. vii. p. 173.) I am not aware of any case in which the subclavian vessels have been wounded by the spicula of a broken clavicle.

[M. Malgaigne, in 1844, met with two cases in which fracture of the clavicle was caused by violent muscular efforts. (See *Traité des Fractures*, &c. t. i. p. 494.)]

The symptoms differ, according as the fracture happens to be situated between the scapular end of the bone and the coraco-clavicular ligaments, or between the insertion of these ligaments, and its sternal extremity. In the first case, the two fragments being fixed by the ligamentous bands, which connect them on one side with the coracoid process, and on the other with the acromion, are but little displaced; and the arm may yet have in the clavicle a sufficient point of support for the execution of its motions. Still, on careful examination, the outer end of the bone will be perceived to be somewhat depressed, and to incline obliquely downwards and forwards, so as to form an angle with the rest of the bone; but if the humerus and shoulder be pushed up, it will readily assume its proper direction. A crepitus is also generally distinguishable, when the surgeon applies his hand

to the place of the fracture, and alternately raises and depresses the shoulder.

[If the fracture have happened just opposite to the coracoid process, and between the attachments of the conoid and trapezoid portions of the coraco-clavicular ligament, the displacement may be even less evident, since each side of the fracture will then be retained in position through its ligamentous connection with the coracoid process.

Mr. R. W. Smith has described the anatomical appearances presented by eight specimens of old fracture near the acromial end of the clavicle in the museum of the Richmond Hospital, Dublin. In three of these in which the bone had been broken between the conoid and trapezoid ligaments, the resulting deformity was very trifling, and limited to a slight increase in the natural curve of this part of the bone. In the other five, however, in which the fracture had been external to both portions of the ligament, the displacement was considerable, much greater, in fact, than the usual description of the symptoms of this accident would lead us to expect. In all the five, the pieces had become joined together at a right angle or nearly so, the fractured end of the external having united with the anterior surface of the internal fragment. The clavicle in consequence had become permanently shortened, and the shoulder was drawn forwards and inwards, so that in one case in which a cast of the body had been taken, the measurement between the sterno-clavicular articulation and the acromion, was found to be nearly an inch less than on the opposite side. In all the eight cases, there was abundant bony deposition on the under surface of the clavicle, and in one the conoid and trapezoid ligaments had become completely ossified, and the clavicle ankylosed with the coracoid process. (See *Treatise on Fractures and Dislocations*, p. 209.)]

In the second and far more frequent case, or that in which the fracture is situated between the insertion of the coraco-clavicular ligaments and the sterno-clavicular articulation, the displacement is much more considerable; and be it remembered, that the external portion of the clavicle is always that which is displaced. The internal part cannot be moved out of its natural situation, by reason of the costo-clavicular ligaments, and of its being drawn in opposite directions, by the sterno-cleido-mastoideus, and pectoralis major, muscles. The external portion, drawn down both by the weight of the arm, and the action of the deltoid muscle, and forward and inward by the pectoralis major, is carried under the internal portion, which projects over it. The broken clavicle no longer keeping the shoulder at a due distance from the sternum, the arm falls forward towards the breast. [The elbow or forearm is usually supported by the opposite hand, and the neck is bent towards the injured side, to relax the sterno-mastoid and trapezius muscles.]

The patient finds it impossible to put his hand to his forehead, because this act makes a semicircular motion of the humerus necessary, which cannot be done while that bone has not a firm point of support. [Abduction of the limb by separating and raising the elbow from the side, is also especially painful and difficult, as it increases the displacement inwards of the outer portion of the fracture.] The shoulder and upper extremity may be observed to be nearer the breast, than those of the opposite

side. The motion of the pieces of bone on one another may be felt, as well as the projection of the end of the internal portion. When the shoulder is moved, a crepitus may also be perceived; but this is productive of great pain, and the diagnosis is so obvious, that it is quite unnecessary.

[Occasionally, the fractured ends remain in contact, either wholly or partially, and then the deformity will not be so evident, but movement of the shoulder will generally produce a crepitus. Sometimes, without being completely separated, they become so placed as to form an angle with each other.

In very rare cases, and when the fracture has been oblique from below upwards and inwards, the external piece has been found to ride over the internal, the direction of the obliquity having, no doubt, occasioned the unusual displacement.

Both clavicles are occasionally broken. Malgaigne records six examples of this double accident, and what is somewhat singular, in three out of the six, the fractures remained ununited. (See *Traité des Fractures*, p. 494.) Fracture of the clavicle is often met with in young children. It is, in fact, more frequent in them than fracture of any other bone.]

For the reduction, the two indications are, to push outwards and backwards the scapular fragment, and to bring it to the level of the sternal part.

The ancients and many moderns, have supposed that, in order to set a fracture of the clavicle, the shoulder should be drawn back, and fixed in that position. The patient was placed on a low stool, so that an assistant might put his knee between the shoulders, which he drew back at the same time with both hands, while the surgeon applied the bandage which was to keep the parts in this position. But when the shoulders are thus drawn towards one another, the scapula is obviously pushed towards the sternum, and with it the external portion of the clavicle, which passes under the internal fragment.

The figure of 8 bandage has commonly been used for maintaining the parts in this position. While the assistant keeps back the shoulders, as above described, the surgeon is to apply one end of a roller to the armpit on the side affected, and then make it cross obliquely to the opposite shoulder, round which it is to pass, and from this to the other shoulder, about which it is to be applied in the same manner, and afterwards repeatedly crossed before and behind. The tightness with which it is necessary to apply this bandage, produces excoriation about the armpits, and the effect is to make the ends of the fracture overlap each other; the very thing which it is wished to avoid. As Boyer remarks, many of the instruments which have been contrived, are only modifications of the figure of 8 bandage, and are not at all better.

Desault advised extension to be made by means of the limb which is articulated with the fractured bone. This is done by converting the humerus into a lever, by carrying its lower end forward, inward, and upward, pushing the shoulder backward, upward, and outward, and putting a cushion in the armpit to serve as a fulcrum.

Desault used to put in the armpit a hair or flock cushion, five or six inches long, and three inches and a quarter thick at its base. Two strings are attached to the corners of the base, which is placed upward: they cross the back and breast, and are tied on the shoulder of the other arm. The cushion

being thus placed in the armpit, and the fore-arm bent, Desault used to take hold of the patient's elbow, and carry it forward, upward, and inward, pressing it forcibly against the breast. By this manœuvre, the humerus carries the shoulder outward, the ends of the fracture become situated opposite each other, and all deformity is removed. An assistant is to support the arm in this position, while the surgeon is to place one end of a roller, nine yards long, in the armpit of the opposite side, and then apply the bandage over the upper part of the arm, and across the back to the same situation. The arm and trunk are to be covered with circles of the roller, as far down as the elbow, drawing the bandage more tightly, the lower it descends. Compresses, dipped in camphorated spirit, having been placed along the fractured bone, Desault took a second roller of the same length as the first, and put one end of it under the opposite armpit, whence it was carried across the breast over the compress and fracture, then down behind the shoulder and arm, and after having passed under the elbow, upward on the breast. Desault next brought it across to the sound shoulder, under and round which he passed it, for the purpose of fixing the first turn. He then conveyed the roller across the back, brought it over the compresses, carried it down in front of the shoulder and arm, under the elbow, and obliquely behind the back to the armpit, where the application began. The same plan was repeated, until all the roller was spent. The apparatus was secured by pins, and the hand kept in a sling.

Boyer's apparatus for fractured clavicles is more simple than that of Desault. The cushion is to be applied under the arm. The apparatus consists of a girdle of linen cloth, which passes round the trunk on a level with the elbow. It is fixed on by means of three straps and as many buckles. At an equal distance from its extremities are placed externally on each side two buckles, two before and two behind the arm. On the lower part of the arm is to be laced a piece of quilted cloth, five or six fingers broad. Four straps are attached to it which correspond to the buckles on the outside of the girdle, and serve both to keep the arm close to the trunk, and from moving either backward or forward.

The principles of treatment inculcated by Desault are excellent; but his manner of bandaging the arm and shoulder is rather complicated, and in women, particularly inconvenient. We learn from Dr. Reese, that in the United States, till very lately, fractured clavicles were almost universally treated on Desault's plan. When the bandage was properly applied, it was found, indeed, adequate to fulfil all the necessary indications; but its complexity, its liability to be deranged, and the pressure it made upon the mammae in female patients, rendered a substitute for it in many cases desirable. In 1816, Dr. S. H. Coale, of Baltimore, therefore invented an apparatus which, in his hands, was entirely successful in bad cases of oblique fracture of the clavicle. It was made of leathern straps and buckles, performing the triple purposes for which Desault's bandage was adapted; and its simplicity as well as permanence, together with its adaptation to female patients, has brought it into general use in the southern states of the Union. An improvement on Desault's mode of applying the bandage has

been suggested by Dr. Stephen Brown, of New York, and is adopted in many parts of the United States. (See *Am. Med. Recorder*, vol. iv.; and *Reese's Am. ed. of this Dict.*) A simple and good apparatus for fractures of the clavicle and those of the neck of the scapula, was proposed many years ago by Mr. Earle. (See *Pract. Obs. on Surgery*, p. 187, &c.) It is also calculated for cases of dislocated clavicle, and other injuries of the shoulder.

[An apparatus was contrived by Heister for making extension upon the clavicle in the required direction, namely, backwards and outwards. It consisted of two pieces of iron or wood joined together in the form of the letter T, the perpendicular part being placed behind the patient's back and fixed with a strap round his waist, the transverse portion passing behind his shoulders and projecting outwards. To the extremities of this part the shoulders were fixed by straps passing round under the axilla. This transverse part of the instrument was so contrived as to be shortened or lengthened at pleasure, according to the width of the patient's shoulders and the degree of extension required.

A drawing of this contrivance will be found in Mr. Lonsdale's *Treatise on Fractures*, p. 214. It seems well calculated to fulfil the indications already insisted upon, but must have been extremely irksome to the wearer.

Mr. Henry Lee has lately contrived a more convenient instrument acting on similar principles. (See *London Journal of Medicine*, Sept. 1857, p. 799.) He recommends it as specially adapted to cases complicated with fractures of the ribs, in which the usual pads and bandages might prove injurious.]

The common figure of 8 bandage, with a sling, may be sufficient when the fracture is external to the coraco-clavicular ligaments; but in other instances, it is prudent to attend more strictly to the indications pointed out by Desault. If surgeons understand why the shoulder should be kept outward, as well as backward and upward, in order to bring the fragments into the best apposition, they will have no difficulty in accomplishing it with a thick wedge-shaped pad, or sling, and a roller; and if not with these means, at all events with Boyer's or Earle's apparatus.

Whatever method is followed, one principal indication is always to prevent the weight of the arm from drawing downward the external fragment; and for this purpose, in England, a sling is generally preferred to bandages, or any of the apparatus sold in the shops.

I cannot quit this subject without cautioning surgeons never to fall into the error of supposing the rising end of a broken clavicle to be that which is displaced. Although this is truly in its right situation, it has often been made by injudicious pressure, to protrude through the integuments, one or two instances of which have fallen under my own observation.

FRACTURES OF THE SCAPULA.

[Fractures of the scapula may be divided into—1, fractures of the body of the bone (including the spinous process and inferior angle, which latter some surgeons have considered separately); 2, fractures of the neck of the bone; 3, of the coracoid process; and 4, of the acromion process.]

Fractures of the body of the scapula are not common; a circumstance explicable by its deep and co-

vered position, and its great mobility. Nor could such an accident arise without considerable direct violence. Fractures of the coracoid process, and of the neck of the scapula, are also rare; for though these parts may appear in the skeleton likely to be often broken, their deep situation in the living subject, and the great mobility of the entire bone, generally saves them. Indeed, as Boyer says, they generally require great violence to break them, and then the contusion of the soft parts is a worse injury than the fracture itself: thus, this author has seen the coracoid process broken by the blow of the pole of a carriage, and the patient lost his life from the violence at the same time inflicted upon all the soft parts about the shoulder. (*Mal. Chir.* t. iii. p. 161.) Fracture of the acromion is generally stated to be more frequent, as might be expected from its prominence and superficial position. Mr. Lonsdale found, however, out of a total of 1901 fractures, eighteen were of the scapula, and of these, eight were of the body, eight of the acromion process, two of the neck, and none of the coracoid process. Those of the acromion and lower angle are more troublesome to keep right; but the most serious cases are fractures of the coracoid process and neck of the bone, which cannot be kept right without great difficulty, and are said to be frequently followed by a considerable stiffness of the arm, inability to raise it, atrophy, and even paralysis.

1. [*Fractures of the body of the scapula* are most commonly transverse or slightly oblique, but sometimes they are vertical, and then the spinous process is included in the fracture. They are always occasioned by direct violence, and therefore are mostly accompanied by much contusion of the soft parts, and sometimes by injury of the thoracic viscera. Unless the fracture be in the neighbourhood of the inferior angle, the displacement is usually slight, but some irregularity or unnatural mobility may generally be distinguished by tracing the margins of the bone, especially the posterior, or a crepitus may be felt when the hand is laid flat on the bone and the patient's arm is moved about. If the fracture be in the vertical direction irregularity will be felt, and crepitus will be produced by tracing the spinous process with the fingers.]

When the lower angle is broken, the serratus major anticus draws it forward, while the rest of the scapula remains in its natural situation; or, if the angular portion be considerable, the teres major and some fibres of the latissimus dorsi contribute to its displacement forward and upward.

The detached portion also remains motionless, while the rest of the scapula is moved, and it is so separated, that no mistake can be made.

Treatment.—When the scapula is fractured longitudinally or transversely, it is merely necessary to fix the arm to the side by means of a bandage, which includes the arm and trunk from the shoulder to the elbow. Thus the motions of the shoulder, which are only concomitant with those of the arm, are prevented. A sling with one or two circles of a roller round the trunk and lower part of the humerus would answer every purpose.

When the inferior angle is broken and drawn downward and forward by the serratus major anticus, the scapula must be pushed toward the fragment by inclining the arm itself inward, down-

ward, and forward, where it is to be kept with a roller. The fragment is also to be kept backward as much as possible with compresses and a roller, and the arm is to be supported in a sling.

In other respects the danger of fractures of the scapula depends less upon the solution of continuity in the bone than the contusion of the soft parts or injury of the thoracic viscera. However, when the fracture is comminuted and the splinters are forced into the subscapularis muscle, abscesses may form under the bone, and, according to Boyer, require a perforation to be made in it (*Mal. Chir.* t. iii. p. 165), a proceeding which I cannot bring myself to think would ever be judicious, as making a depending opening in the soft parts must be far better practice. In military surgery the scapula is often injured by sabre-cuts; but, as Dr. Hennen remarks, this bone, when preserved from motion, is found in these cases to unite with great readiness and without future inconvenience. (*Principles of Military Surgery*, p. 48, ed. 2.)

2. *Fracture of the neck of the scapula.*—[This is understood to mean fracture of the narrow part of the bone opposite the notch in the superior costa, so that the coracoid process with the glenoid cavity is separated from the rest of the bone.]

When this part of the scapula is fractured, the weight of the arm makes it drop down so considerably as to give the appearance of a dislocation; but the facility of lifting the humerus upward, the crepitus, and the falling of the limb downward again immediately it is unsupported, are circumstances clearly marking that the case is not a dislocation. According to Sir Astley Cooper, the crepitus is best perceived through the medium of the coracoid process. The degree in which the glenoid cavity and the head of the humerus descend, he observes, depends very much upon whether the ligaments between the under part of the spine of the scapula and the glenoid cavity are lacerated or not. (*On Dislocations*, &c. p. 459.)

[The descent of the glenoid cavity towards the axilla must also depend very much on the rupture of the coraco-clavicular ligaments, without which it can scarcely take place to any appreciable extent.

This accident is extremely rare, so much so that some surgeons, among whom may be mentioned Mr. South, doubt that it ever occurs. (See *Translation of Chelius*, vol. i. p. 549.) Sir A. Cooper, however, relates two cases which do not appear to admit of any doubt, and a dissection by Duverney has proved the possibility of its occurrence. Recently also Mr. Pirrie speaks of having seen three cases in which "all the symptoms were exceedingly well marked." (*Principles and Practice of Surgery*, p. 156.)]

The treatment of a fracture of the neck of the scapula consists in keeping the head of the os humeri outwards by means of a thick cushion in the axilla, in keeping the glenoid cavity and arm raised with a sling, and in preventing all motion of the arm by binding it to the trunk with a roller. In some of these cases the apparatus proposed by Mr. Earle might be useful. (*Pract. Obs. in Surg.* 1823.)

Sometimes great pain and a crepitus are experienced on moving the shoulder joint after an accident, and yet the spine, the neck of the scapula, and all the above parts are not broken. In this

circumstance it is to be suspected either that a small portion of the head of the os brachii, or a little piece of the glenoid cavity of the scapula, is broken off, which latter occurrence, I think, is not very uncommon.

[M. Malgaigne is of opinion that the symptoms of fracture of the neck of the scapula, as described by Sir A. Cooper, are more likely to be caused by fracture of a portion of the glenoid cavity, accompanied by dislocation downwards into the axilla. (See *Traité des Fractures*, &c. t. ii. p. 551.)]

3. *Fracture of the coracoid process.*—[This fracture is always caused by direct violence, and therefore is likely to be accompanied by severe contusion of the soft parts, the swelling from which may obscure the nature of the injury. Indeed, the mischief done to the soft parts is often of more importance than the fracture, as in the case related by Boyer, which terminated fatally, and which has been already referred to.

When the coracoid process is fractured, the pectoralis minor, coraco-brachialis, and short head of the biceps concur in drawing it forward and downward, so that its apex will generally be felt lower down than on the sound side, and it may be made to move while the rest of the scapula is fixed. If, however, the fracture be at the root of the process, the displacement may be less evident, as it may remain attached to the under surface of the clavicle by the coraco-clavicular ligaments, and unless these fibres are ruptured when the fracture takes place, its descent may be prevented. The attempts of the patient to move his arm will occasion severe pain.]

Treatment.—When the coracoid process is fractured, the muscles attached to it are to be relaxed by bringing the arm forward towards the breast and confining it there in a sling, while the shoulder is kept downward and forward, and a compress confined just under the broken part with a roller.

[Union by ligamentous substance is all that can be expected.]

4. *Fracture of the acromion* is most commonly produced by a blow or fall on the shoulder. The fracture is almost always transverse, and may occur either towards the apex or base of the acromion. The outer fragment is drawn downward by the weight of the arm and the contraction of the deltoid muscle, while the trapezius and levator scapulæ draw the rest of the bone upward and backward. The roundness of the injured shoulder is diminished, and part of the attachment of the deltoid being broken off, the head of the os humeri sinks towards the axilla as far as the capsular ligament will permit.

[If the fracture be very near the root of the process, the depression will be greater, for then the clavicle will fall as well, and allow the whole anterior part of the muscle to be displaced downwards. (*Lonsdale, On Fractures*, p. 201.)]

On tracing the acromion from the spine of the scapula to the clavicle, the surgeon will feel a depression just at their junction. The distance from the sternal end of the clavicle to the extremity of the shoulder is lessened. The natural form of the shoulder may be restored by raising the arm by the elbow, but the deformity returns immediately the arm is suffered to fall again. The accident may be distinguished from a dislocation, if the surgeon raise

the shoulder by pushing the humerus upwards, when a crepitus will be perceptible to the surgeon's hand applied over the acromion on the limb being rotated. The patient feels a sense of weight, as if his arm were dropping off, and there is but little power to raise the limb.

Treatment.—The fractured acromion requires the arm to be so raised that the head of the os brachii will push up the acromion, while an assistant pushes the scapula forward and downward in a contrary direction to that of the arm. To maintain this position, a circular bandage is to be applied round the arm and body.

Desault used to apply also a wedge-shaped cushion under the axilla before putting on the bandage, in order to make the head of the os brachii project more upward on bringing the arm near the side; but Sir Astley Cooper finds that a cushion so placed does harm by throwing the head of the os humeri outward, and widely separating the acromion from the spine of the scapula. He approves of raising the elbow and keeping the arm fixed. He also relaxes the deltoid muscle by means of a cushion put between the elbow and the side, the elbow inclining a little backwards; the limb is to be bound to the chest in this position with a roller. The union may take place by bone, but, owing to the difficulty of maintaining the coaptation, the uniting substance is generally ligamentous. (See *Sir A. Cooper, On Dislocations*, p. 455.)

[FRACTURES OF THE HUMERUS.]

[The humerus may be broken at any point of its length or at either of its extremities. The fractures of each of these divisions of the bone differ so much in their characters that each will necessarily require to be separately considered.]

Fractures of the Upper Extremity of the Humerus.

[The injuries occurring to this portion of the bone must again be subdivided into—1, *fractures of the surgical neck*; 2, *fractures of the anatomical neck*; and 3, *fractures of the tuberosities*. The surgical neck is that part of the bone which is bounded above by the tuberosities, and below by commencement of the insertion of the muscles attached to the margins of the bicipital groove, viz. the pectoralis major, the latissimus dorsi, and teres major. The anatomical neck is the circular narrowing which separates the tuberosities from the head. The term *extracapsular* has also of late years been applied to designate the former, and *intracapsular* the latter class of cases. Separation of the epiphysis from the shaft of the bone not unfrequently happens in young persons, and this should be considered as a variety of the fracture of the *surgical*, and not of the *anatomical* neck, as it was described by Sir A. Cooper, since the line of union of the epiphysis with the shaft is situated below the tuberosities. Sir A. Cooper described the line of union of the epiphysis as the anatomical neck, while he spoke of the surgical neck as extending from the articulation as low down as the insertion of the coraco-brachialis and deltoid muscles. This description, from so eminent an authority, has given rise to considerable confusion, but it will be understood that in the present edition of this dictionary the terms are used strictly in accordance with the limitations above given.]

1. *Fracture of the surgical neck.*—[This is the most frequent injury met with at this end of the bone; it is generally caused either by a direct blow, or by a fall on the shoulder with the arm in contact with the side.]

An acute pain is experienced at the moment of the fall; sometimes the noise of something breaking is heard. There is always a sudden inability to move the limb, which, left to itself, remains motionless. But, on external force being applied, it readily yields, and admits of being moved with the greatest ease in every direction. Such motion is attended with severe pain, and if carried too far may cause ill consequences, as has been observed in patients in whom the fracture has been mistaken for dislocation.

Fractures of the neck of the humerus are always attended with displacement, produced by the action of the pectoralis major, latissimus dorsi, and teres major, which, being attached to the lower portion near its superior extremity, draw it first inward and then upward, in which last direction it is also powerfully urged by the biceps, coracobrachialis, and long portion of the triceps. In this case the superior portion itself is directed a little outward by the action of the infra-spinatus, supra-spinatus, and teres minor, which make the head of the humerus perform a rotatory motion in the glenoid cavity.

Below the acromion a depression is remarkable, always situated lower down than that which attends a dislocation. If we place one hand on the head while the lower part of the bone is moved in various directions with the other hand; or if, while extension is made, an assistant communicates to the bone a rotatory motion, the following circumstances are perceived:—1, the head of the humerus remains motionless; 2, a more or less distinct crepitus is felt arising from the two ends of the fracture rubbing against each other. These two symptoms are characteristic of the accident, but the swelling of the joint may prevent us from detecting them.

Sometimes there is no displacement of the ends of the fracture, and then, as most of the symptoms are absent, the diagnosis is more difficult. In general, however, the ends of the fracture are displaced, and in this circumstance it is the lower one which is out of its proper position, and not the upper one, which is of little extent, and is not acted upon by many muscles.

The displacement is generally not very perceptible in regard to length, unless the fracture be very oblique, and its pointed spicula irritate the muscles and make them contract with increased power; or unless the blow, which was violent, continued to operate after the bone had been broken and forced the ends of the fracture from their state of apposition. In this way the body of the humerus has been drawn or driven upward, so as to protrude through the deltoid muscle and integuments far above the height of the head of the bone.

But commonly, as Petit observes, the weight of the limb powerfully resists the action of the muscles, and the displacement of the fracture is more liable to be transverse. In this circumstance the lower end of the fracture is displaced inward, and rarely in any other direction. In the most frequent case the elbow is separated from the trunk, and cannot be brought near it without pain.

According to Sir A. Cooper, the upper end of the main portion of the humerus sinks into the axilla, where it can be felt, and the deltoid is drawn down by it so that the roundness of the shoulder is diminished. (*On Dislocations, &c.* p. 459.)

When the accident is produced by a direct blow or fall on the fleshy part of the shoulder, the deltoid is sometimes contused and affected with ecchymosis. Blood may even be effused from some of the ruptured articular veins or arteries, and form a collection.

[M. Malgaigne, on the other hand, states that in a great majority of the cases which he has met with the deformity was very trifling, and the fractured ends were seldom completely separated from each other. Out of more than twenty examples he only saw two in which there was "sensible and recognisable" displacement. (See *Traité des Fractures*, p. 515.)]

Fractures of the neck of the humerus have, not unfrequently from want of attention, been confounded with dislocations, notwithstanding the difference in the diagnostic symptoms of the two accidents.

On this part of the subject some admirable observations were made by Dupuytren. Every person, he remarks, who meets either with a dislocation, or a fracture of the upper end of the humerus, has fallen upon the corresponding side of the body; but the position of the limb at the moment of the fall has not been the same in both cases; and this difference commonly determines the kind of injury which is to follow, and furnishes the means of recognising it. If, in falling, the patient separates his arm from the side, and puts out his hand to weaken the effects of the fall, the accident will be a dislocation of the head of the humerus, without fracture. On the contrary, if the arm be kept close to the side, as in an unexpected fall, or when the hand is confined in the breeches pocket, the weight of the body then acts upon the cushion of the shoulder, and if there is any displacement, it arises from a fracture of the head, or upper part of the humerus. If the case be a dislocation, the hand having struck the ground is usually marked by mud, dirt, abrasions, or ecchymosis: if a dislocation, the violence having operated directly on the cushion of the shoulder, the hand is free from those appearances, and the part of the dress covering the deltoid presents traces of having come in contact with the ground; or the skin of the shoulder exhibits marks of contusion. In dislocation, ecchymosis is situated at the internal and forepart of the arm; in fracture, it is upon the very cushion of the shoulder. In dislocation, ecchymosis is less frequent than in fracture. In both accidents the acromion is prominent, but more so in dislocation; and in fracture the deltoid is shortened, and, as it were, swollen. In fracture the vacancy under the acromion is less than in dislocation, and the prominence in the axilla much less. In dislocation there is no crepitation — no ready movableness of the limb, as in fracture. Dislocation requires greater efforts for its reduction, for the maintenance of which it is sufficient to confine the arm close to the side; but in fracture of the upper part of the humerus an apparatus is indispensable to hinder the muscles from reproducing the displacement. A fracture, without displacement, may be mistaken for a simple contusion.

The crepitus and mobility felt in the injured part, on rotating the lower portion of the humerus, are the only means of ascertaining the nature of the accident; but care must be taken not to be deceived by the kind of crackling felt in examining the shoulder after a severe contusion, and which arises from inflammation of the articular surfaces, and a deficiency of synovia. (See *Dupuytren, in Clin. Chir.* t. iii. p. 106.)

[The position of the limb at the moment of the fall, and the situation of the ecchymosis, are however, by no means such reliable signs as Dupuytren supposed them to be, for it is now known that dislocations are also not unfrequently caused by falls upon the shoulder, with the arm close to the side. (See *DISLOCATION OF THE SHOULDER.*)]

There is a class of cases, however, in which the symptoms are by no means so distinct as usual, and this is when the fragments have become impacted, the upper end of the shaft having been driven into the cancellated texture of the head and tuberosities. In these cases the fractured surfaces may be only very slightly movable on each other, and there may be, therefore, great difficulty in detecting crepitus; the deformity may be only trifling, and the head of the bone may even be felt to move with the shaft when the latter is rotated.

Mr. R. W. Smith thus describes the signs of this somewhat obscure injury:

"When a person falls on the upper and outer part of the shoulder, and at once loses the power of executing the motions natural to the articulation, when none of the characters of luxation, or of the ordinary fractures of the neck of the humerus are present, and where at the same time there is a certain degree of deformity, which, though slight, it is by no means easy to remove, and an unusual difficulty in detecting crepitus, we have grounds for suspecting the existence of an impacted fracture of the neck of the bone.

"In order, however, to form a more decided opinion as to the nature of the lesion which the bone has suffered, let the surgeon with both hands grasp the head of the bone with firmness sufficient to maintain it as nearly as possible in a fixed position, while an assistant rotates the elbow; by this method crepitus can be produced in the great majority of cases." (*Treatise on Fractures, &c.* p. 186, 1847.)

In young persons, instead of fracture, separation in the line of union of the epiphysis with the shaft most commonly happens, but the symptoms of this accident do not differ very materially from those of the ordinary fracture of the surgical neck. The head of the bone remains in the glenoid cavity; a slight depression is seen beneath it, and it remains motionless when the shaft of the humerus is rotated. The upper extremity of the shaft of the bone is drawn inwards by the muscles which constitute the folds of the axilla, and forms an abrupt projection beneath the coracoid process, but it is seldom drawn so far inwards as to enable it to clear completely the surface of the superior portion, and consequently there is but little displacement as regards the length of the bone. The projection of the upper surface of the shaft feels smoother than in an ordinary fracture, and the crepitus is less rough and grating than usual. (See *R. W. Smith*, op. cit. p. 200.)

It will be found that these are as nearly as possible the symptoms referred by Sir A. Cooper

to the "fracture through the tubercles or at the anatomical neck"—(See *A. Cooper, On Fractures &c. ed. by B. Cooper, p. 427*)—but which really belong to the fracture of the surgical neck, or to the epiphysary disjunction, which is the same thing.]

Treatment of fractures of the surgical neck of the humerus.—The reduction takes place of itself, on employing a very little force, methodically directed. If the surgeon put his hands on the situation of the fracture, it is rather to examine the state of the ends of the broken bone, than to accomplish a thing seldom required, namely, what is implied by the term coaptation.

In the treatment, the three indications are,

1. To render the arm and shoulder immovable :
2. To bring outward the lower end of the fracture :
3. To draw downward the same.

[These objects may be accomplished by the application of four splints; one on the anterior, one on the posterior, one on the outer, and one on the inner side of the limb; the three first mentioned should extend as high as the acromion, but that on the inner side must of course cease at the axilla. These splints may be retained either by a bandage or by straps and buckles, and when they have been adjusted, a wedge-shaped cushion should be placed, with its base upwards, in the axilla, and the arm then bandaged to the side. The cushion is for the purpose of pressing outwards the lower end of the fracture, and to prevent its being drawn inwards towards the chest by the action of the muscles. Sir A. Cooper recommended two splints, one anteriorly and one posteriorly, with a pad in the axilla, and the arm fixed to the side by the clavicular bandage; the hand and not the elbow to be supported by a sling, as if the elbow be raised, the upper end of the bone projects forward, or the fragments, if the fracture is oblique, may be made to overlap, while, on the other hand, if the arm is allowed to hang by the side unsupported at the elbow, the weight of the arm is a constant source of extension upon the broken end of the bone. (*On Dislocations, p. 430, 434.*)

Mr. Tyrrell states that in one instance, in which he could not otherwise succeed in removing the deformity, he found the bone maintained its natural position when raised and supported at a right angle with the side; he therefore applied a rectangular splint, one portion of which rested against the side of the patient whilst the arm reposed upon the other part, and in this way he succeeded in retaining the pieces in their proper relative positions.

This case is worthy of attention, for the position, though no doubt irksome to the patient, is very advantageous as regards the position of the upper fragment, when as very frequently happens, it is directed outwards by the action of the capsular muscles; and since, from the small size of this piece and its deep situation, it is almost impossible to act upon it directly, the only way to remedy the deformity is to raise the shaft of the bone until the axes of both pieces are made to correspond.]

2. *Fracture of the anatomical neck of the humerus.*

—Indisputable facts prove the possibility of the anatomical neck of the bone being fractured, and C. Larbaud showed Bichat the humerus of a young man, aged 17, the head of which bone was accurately detached from its body by a division which had passed obliquely through the upper part

of the tuberosities. Another example, proved by dissection, was recorded by Delpech. (*Chirurgie Clinique.*) An instance of this kind was pointed out to me in the spring of 1821, in St. Bartholomew's Hospital. The patient was a boy, whose elbow had been strongly kept up, on the supposition that the case was a fracture of the neck of the scapula, and, consequently, the irregular end of the humerus formed a remarkable projection in front of the acromion, yet capable of being pushed back, where, however, it would not remain.

[In addition to these cases, there is now abundant evidence of the occurrence of this injury, though it is much more rare than fracture of the surgical neck. It may be completely *intracapsular*, the head of the bone being detached from the shaft and tuberosities, and lying loose in the cavity of the joint; or it may include a portion of one or both tuberosities, and it will then be partly an *intracapsular*, and partly an *extracapsular* fracture. The signs of this injury are somewhat obscure; it is always caused by direct violence, such as a severe blow or fall on the point of the shoulder; after which the patient loses all power to move the limb, and though the surgeon can readily do so, yet very severe pain is caused by the attempt. Usually there is not much displacement, the muscles attached to the tuberosities counteract the influence of those inserted into the margins of the bicipital groove, and retain the upper end of the bone in its place. The fractured surfaces, therefore, remain in contact, and crepitus may be felt when the arm is moved.

The impairment of the motions of the joint and crepitus are in fact, as Mr. Smith observes, almost the only direct symptoms upon which the surgeon can depend, but his opinion will be strengthened by the absence of the signs of any of the other injuries occurring in this region, and by finding that all the neighbouring prominences of bone retain their proper relations to each other. Sometimes, however, the shaft of the bone is drawn a little forwards and inwards towards the coracoid process, and there will then be a projection at the anterior part of the joint, and a corresponding depression posteriorly under the acromion. In most cases there is severe contusion of the soft parts covering the joint, and the swelling arising from this cause may add materially to the difficulty of the diagnosis.

In this case also, as in the *extracapsular* fracture, the fragments may become *impacted*, but it is now the superior piece which is the smaller, and which is driven into the inferior or larger between the tuberosities, one or other of which processes is usually at the same time broken off or bent outwards from the shaft. Mr. R. W. Smith thus describes the symptoms of the *intracapsular impacted* fracture, which are more marked than those of the simple or non-impacted variety. "The arm is slightly shortened, the acromion process projects more than natural, and the shoulder has lost to a certain extent its rounded form; the upper extremity of the shaft of the humerus is approximated to the acromion, and the entire of the globular head of the bone cannot be felt. In consequence of the accompanying fracture of the tuberosity crepitus can be readily detected, when the shoulder is grasped with moderate firmness and the arm rotated. The absence of a rounded tumor in the axilla, and the

impossibility of feeling the glenoid cavity, are sufficient to enable us to distinguish this injury from luxation." (Op. cit. p. 188.) This author describes one very singular case, in which the head of the bone was found to be completely reversed in the articulation, so that its fractured surface was directed towards the glenoid cavity, and the cartilaginous articulating surface thrown towards the shaft, and driven to a considerable distance into the cancellated tissue between the tubercles (p. 194). M. Nélaton refers to two similar cases. (See *Élém. de Pathol. Chir.* t. i. p. 736.)

In the intracapsular fracture, accompanied with impaction, the fragments are retained in so firm and continuous contact with each other, that direct osseous union can take place without much difficulty. But in the non-impacted variety the superior fragment is cut off from all connection with the surrounding tissues, and is in danger of perishing for want of nutrition, and acting as a foreign body in the articulation. In some, though fortunately very rare instances, this has been found to occur, and the head of the bone has been eliminated from the joint by suppuration.

Notwithstanding, however, these unfavourable circumstances, even where there is no impaction, osseous consolidation may still be accomplished. But it is highly probable, that in the cases in which this fortunate result has occurred, the vascular communication between the fragments has not been entirely cut off, but that they have remained partially connected together by the attachment of the capsular ligament, the vascular supply derived from which proves adequate to the preservation of the vitality of the head of the bone, although it may not be sufficient to enable it to take a very active part in the process of osseous union. (R. W. Smith, op. cit. p. 190.) In all cases, indeed, whether impacted or not, the reparation of the injury is chiefly accomplished by the lower fragment, which throws out bony matter in great profusion, so as to incase, as it were, the superior fragment. (See also A. Cooper, *On Dislocations*, p. 428.)

Treatment of fractures of the anatomical neck of the humerus.—In the non-impacted intracapsular fracture no coaptation is required, since the parts remain in contact, and are usually in their natural situation or nearly so. The object of the treatment, therefore, is merely to keep the parts at rest as completely as possible while union is going on, and for this purpose all that is necessary in most cases is to bandage the arm to the side and support the forearm in a sling. The pad in the axilla should not be used, since by throwing outwards the shaft of the bone it would tend to separate the fragments, and so to prevent osseous union, which can in this case scarcely be expected to take place unless the surfaces are maintained in close and continuous apposition.

The impacted intracapsular fracture always unites with a certain amount of deformity, which it would be imprudent to attempt to obviate, for even if we succeeded, we should thus materially diminish the chance of osseous consolidation. It is sufficient, therefore, to keep the arm at rest in the way above recommended, but to inform the patient at the same time, that a certain degree of deformity and of impairment of the motions of the joint will be a permanent result of the injury. (R. W. Smith, op. cit. p. 191.) Mr. Smith gives

a drawing of a bone in which this fracture had occurred, and which he had an opportunity of examining some years after the accident. Firm union has taken place; the head of the bone is deeply sunk into the shaft, the upper extremity of which, with the tuberosities, appears as if bent outwards. In the museum of St. Mary's Hospital is a humerus which is almost identical in appearance with this drawing.

In all these cases, passive motion should be employed as soon as the union has become firm.]

3. [*Fracture of the greater tuberosity*, by which that process is detached from the rest of the bone, occasionally happens. In this injury the pieces are widely separated, the tuberosity being drawn backwards by the muscles attached to it, and the shaft of the bone forwards and inwards by the pectoralis major and subscapularis. The result is a great increase in the breadth of the shoulder from before backwards, while its rotundity is at the same time diminished, and the acromion becomes more prominent than natural. On a closer examination, two prominences may be distinguished, separated by an intervening depression. The anterior of these, situated beneath the coracoid process, belongs to the head of the bone; it will therefore be felt to move when the arm is rotated at the elbow. The posterior is the detached tuberosity, and does not follow any movement communicated to the shaft of the bone. Crepitus may perhaps be produced when the shoulder is compressed so as to bring the two portions of bone into contact. The patient cannot raise his arm by his own efforts beyond the horizontal line; it is usually separated from the side, but can be approximated to it without difficulty.

When the head of the humerus is situated beneath the coracoid process, it is questionable whether the accident might not with greater propriety be considered as a dislocation of the shoulder-joint complicated with fracture of the tuberosity. (See DISLOCATIONS, ante, p. 520.) The tuberosity may, however, doubtless be broken off without so great a displacement of the rest of the bone as has been here assigned to it, in accordance with the description given by Mr. Smith.

The treatment consists in fixing the shoulder, and drawing backwards the shaft of the bone by the figure of 8 bandage, and binding the arm to the side. (See R. W. Smith, *On Dislocations*, &c. p. 176, and also A. Cooper, p. 435.)

[*Fracture of the neck of the humerus with dislocation of the head of the bone.*—This accident, according to Sir A. Cooper, is generally caused by a violent fall on the shoulder. By the first impression of the accident the os humeri is dislocated, and by a second the neck of the bone is broken, and the head is detached and lodges in the axilla. The symptoms bear some resemblance to those of the simple dislocation downwards, inasmuch as the head of the bone may be felt in the axilla when the arm is raised; but it cannot, as in dislocation, be made to move when the arm is rotated at the elbow. There is also less hollow below the acromion, because the broken extremity of the shaft of the bone quits the head and becomes lodged in the glenoid cavity of the scapula. An indistinct crepitus may be produced by the friction of these latter parts against each other. The injured arm

is shorter than its fellow, and is usually drawn somewhat inwards by the action of the coracobrachialis and deltoid muscles. The nature of the accident will often be much obscured by the effusion of blood, and by the inflammation which speedily follows. Sir A. Cooper mentions four cases in which death ensued at some distance of time after the accident, and the parts were examined. In two the fracture was at the anatomical neck, and within the capsule; in the other two it appears to have been situated below the tubercles. In all four a more or less perfect joint had been formed between the glenoid cavity and the shaft of the humerus, and the head had become connected, either by bone or ligament, with the inferior costa of the scapula or with the subscapular fossa. All the lower movements of the shoulder were tolerably perfect, but the arm could not be raised beyond a right angle with the body. (*On Dislocations, &c.* p. 418.) M. Malgaigne records eight cases of fracture at the anatomical neck accompanied with dislocation; two of the eight, however, are the same which have been already referred to as related by Sir A. Cooper. In four the head was displaced into the axilla; in two it had escaped from the capsule backwards on to the dorsum of the scapula, and in the remaining two, forwards under the clavicle. (See *Malgaigne, Traité des Fractures, &c.* t. ii. p. 548.)

In the treatment, it is useless to attempt to reduce the dislocation of the head of the bone; but we should endeavour, as far as possible, to retain the fractured end of the shaft in apposition with the glenoid cavity. For this purpose Sir A. Cooper recommended a pad to be placed in the axilla, the shoulder to be steadied and drawn back by the clavicular or figure of eight bandage, the arm to be bound to the side, and the forearm supported in a sling.

When the inflammation has been reduced and the swelling has subsided, passive movement should be assiduously employed, in order that the movements of the new articulation may be rendered as extensive as possible. There is always some fear that the head of the bone, being completely separated from all its connections, may become necrosed, and so excite inflammation and abscess: in the majority of cases, however, it does not lose its vitality, but remains quiescent in its new situation, and contracts adhesions to the surrounding parts. Sometimes the tuberosities, or the upper part of the shaft, are severely comminuted, and the patient may even lose his life from the severity of the injury and the inflammation to which it gives rise.]

Fractures of the Shaft of the Humerus.

Fractures of this portion of the bone may be transverse or oblique, simple or compound. When the fracture takes place above the insertion of the deltoid muscle, the inferior portion is drawn outwards and upwards by that muscle, while the superior portion is drawn inwards by the action of the pectoralis, latissimus dorsi, and teres major muscles. When the fracture is below the insertion of the deltoid, the deformity will be in the opposite direction, as that muscle will then tend to draw outwards the superior fragment. Transverse fractures in the inferior third of the bone are attended with but little displacement, for the brachialis anticus and the triceps, being attached

posteriorly and anteriorly to both fragments, counteract one another, and permit only a slight angular displacement.

Oblique fractures, however, are usually attended with displacement, whatever be the part of the bone broken. The inferior portion being drawn upward by the action of the biceps and long portion of the triceps, and if above the centre of the bone by the deltoid and coraco-brachialis also, glides easily on the superior, and passes above its lower extremity.

The shortening and change in the direction of the limb, the crepitus, which may be very distinctly perceived by moving the broken pieces in opposite directions, the pain, and impossibility of moving the arm, &c. joined to the history of the case, render the diagnosis sufficiently plain.

In a simple fracture of the shaft of the humerus, the prognosis is generally favourable; but fractures near the elbow are liable to be followed by more or less stiffness of the joint, often very difficult of removal.

Treatment of fractures of the shaft of the humerus.—In ordinary fractures of the humerus, extension, if necessary, should be made by an assistant, who draws the lower portion of the bone downward and bends the elbow, while the surgeon applies a roller round the limb. An external splint should then be applied, extending from the acromion to the outer condyle, and being lined with a soft pad, it cannot hurt the limb by pressure. An internal splint should reach from the margins of the axilla to a little below the inner condyle, and should also be well guarded with a pad, filled with tow or any other soft material.

Some surgeons are content with the application of two splints, but though the two above described are those on which we are to place the greatest reliance, yet, as the cylindrical form of the arm conveniently allows us completely to include this part of the limb in splints, I consider the employment of four better: one on the outside, one on the inside, one on the front, and another on the back of the arm. These are to be carefully fixed in their respective situations by means of tape or a roller. Throughout the treatment, the elbow and whole of the forearm are to be quietly and effectually supported in a sling.

[In doing this, care should be taken not to do more than support the elbow, for if it be pressed upwards, the broken ends may be made to overlap, especially if the fracture be oblique. On the other hand, if the elbow be left entirely unsupported, the weight of the limb may cause an undue separation of the fragments, and thus prevent consolidation taking place. This is probably the principal reason why ununited fracture is so much more frequent in the humerus than in other bones.]

In the fracture above the insertion of the deltoid, where the upper fragment is displaced inwards, a cushion may be placed in the axilla after the splints are applied, in order to throw outwards this portion of the bone.

In very oblique fractures below the deltoid, there is sometimes considerable difficulty in preventing overriding of the fragments. In a case of this kind the splint devised by Mr. Lonsdale, for the purpose of making permanent extension, may be employed with advantage. It consists of a thin bar of iron, an inch and a half wide, to be used as an internal splint, and so contrived at its

lower end as to admit of the elbow being firmly fixed to it, while at its upper end is a crutch which fits underneath the axilla, and which slides up and down by means of a screw. By screwing the crutch upwards, so as to press against the axilla, while the elbow is firmly fixed to the lower end of the apparatus, permanent extension may be kept up. Anterior, posterior, and external splints may be applied at the same time as usual. (See *Lonsdale, On Fractures*, p. 173.) In all fractures of the humerus it is desirable to retain the arm in contact with the side, by a few turns of a roller round the body.]

Fractures of the lower extremity of the humerus.

[The injuries occurring to this portion of the bone may be divided into—1. *Fracture just above the condyles*; 2. *Fracture of the internal condyle*; 3. *Fracture of the external condyle*.

1. *Fracture just above the condyles* is most frequently caused by a blow or by a fall on the elbow, but it is occasionally the result of a fall on the palm of the hand, by which the bones of the forearm are forcibly driven against the lower end of the humerus. This accident is often met with in children, but, in them it is not, strictly speaking, a fracture, but a separation of the epiphysis from the shaft of the bone, which usually takes place.

In most cases, the lower fragment is drawn upwards behind the shaft of the bone by the action of the triceps extensor on the olecranon process, and an unnatural prominence is thereby produced at the posterior aspect of the arm, which, without due caution, might cause the injury to be mistaken for a dislocation of the bones of the forearm backwards. This displacement will be produced all the more readily if the direction of the fracture happen to be oblique downwards and forwards, which Sir A. Cooper thinks is most frequently the case. The fracture may be distinguished from the dislocation by the greater mobility of the arm, and by the crepitus which its movement will produce in the fracture, also a moderate degree of force will remove the deformity, but it returns as soon as the extension is discontinued; whereas, in dislocation, much greater force is required, but after it has been reduced, the displacement has no disposition to recur. In addition to these distinctions, M. Malgaigne observes, that however much the olecranon may project posteriorly, it is never more distant from the condyles than natural, if it be a fracture, but is far removed from them in dislocation; and that in fracture, the counter-projection in the front of the arm is less broad and more rounded, and is situated above the bend of the elbow, while in luxation it is below it; also, that in measuring the arm from the acromion to the condyles, there is a shortening in fracture which does not exist in dislocation. (*Traité des Fractures*, &c. vol. i. p. 554.)

In all cases where the fracture is transverse, or oblique in the direction indicated by Sir A. Cooper, the rule above laid down respecting the displacement of the fragments will be found to hold good; an occasional exception may, however, be met with when the bone has been broken obliquely in the opposite direction, namely, downwards and backwards, since it is then almost impossible for the lower piece to pass behind the upper.

M. Malgaigne relates an instance of this obliquity, in which the upper piece descended behind

the lower, and became lodged against the summit of the olecranon beneath the insertion of the extensor tendon. (Op. cit. p. 553.) This case well exemplifies the manner in which the oblique direction of a fracture may modify the displacement which the action of the muscles would otherwise tend to produce.

A modification of this accident, first noticed by Desault, is sometimes met with, in which the fracture above described, is complicated by a longitudinal division separating the condyles, and extending downwards into the elbow-joint, so that there will be three separate pieces of bone and two fractures.

The fracture of the condyles may be more or less oblique, and the pieces may be equal or unequal in size.]

In this complication the deformity is greater, and the fractured part is more movable. When pressure is made, either before or behind, on the track of the longitudinal fracture, the two condyles, becoming further separated from each other, leave a fissure between them, and the fractured part is widened. On taking hold of the condyles, and moving them in different directions, a distinct crepitus is perceived.

[In all fractures in the immediate vicinity of the elbow, swelling rapidly supervenes, and unless the part can be examined very shortly after the accident, there may be great difficulty in forming an exact diagnosis.]

Treatment.—The treatment advised by Sir Astley Cooper, consists in bending the arm, drawing it forwards so as to reduce the parts, and then applying a roller. The best splint for this case is one formed at right angles, the upper portion of it being placed behind the upper arm, and the lower under the forearm. He also directs the application of a splint to the fore part of the upper arm. The splints are to be fixed with straps; evaporating lotions used; and the arm kept in a bent position in a sling. In a fortnight, if the patient be young, and, in three weeks, if he be an adult, passive motion may be gently employed for the purpose of hindering ankylosis. (*On Dislocations*, &c. p. 464.)

When there is also a fracture through the condyles into the elbow joint, the detached fragments being drawn in opposite directions by the muscles of the arm and forearm, commonly remain unmoved between these two powers, and are but little displaced. External force may, however, put them out of their proper situation, and they may then be displaced forward or backward, or they may separate from each other sideways, leaving an interspace between them. Hence, the apparatus should resist them in these four directions; and this object is easily accomplished by means of four splints, kept on with a roller. The two lateral splints are particularly necessary, when the condyles are separated from the body of the bone, with an interspace between them. If one of them be still continuous with the humerus, no splint on this side will be requisite.

[Even when there is no separation, its occurrence should be provided against by a moderate degree of lateral compression, though the side splints may not then be required. For this purpose, a bandage round the elbow, applied before the antero-posterior splints are adjusted, will generally be found sufficient. Often, when there is much swell-

ing and effusion into the joint, it will be better not to apply any apparatus for a few days; but to keep the arm at perfect rest upon a pillow, and to apply leeches and evaporating lotions until the inflammation has subsided.]

Desault recommends the front and back splints to be flexible at their middle part, which should be applied to the bend of the arm and elbow.

The old writers considered the communication of a fracture with a joint a fatal kind of complication. Swelling and inflammation of the adjacent parts; continuance of pain after the reduction; large abscesses; even mortification of the softer parts, and caries of the bones, are, according to such authors, the almost inevitable consequences of these fractures, and ankylosis the most favourable termination. Paré, Petit, Heister, Duverney, all give this exaggerated picture. However, the experience of these and other fractures into joints, amply prove that this representation is magnified beyond truth.

2. [*Fracture of the internal condyle.*—The internal condyle consists of an articular and a non-articular portion, to which the terms trochlea and epitrochlea are now frequently applied. The fracture may merely implicate the non-articular prominence or epitrochlea, or the whole of the condyle with its trochlear surface may be broken off obliquely from the rest of the bone.

Sir A. Cooper speaks of the latter fracture as of frequent occurrence, while Malgaigne on the other hand considers it to be extremely rare, and states that he has never himself met with an instance. The French surgeon, however, records several examples of the fracture in which the epitrochlea alone is broken off. According to Sir A. Cooper, the symptoms are the following: the ulna appears dislocated because it projects behind the humerus with the broken condyle when the arm is extended; but it resumes its natural situation on bending the arm. By grasping the condyles, and bending and extending the forearm, a crepitus is perceived at the internal condyle. When the arm is extended, the lower end of the humerus (*i.e.* the external condyle) advances upon the ulna so as to be felt at the anterior part of the joint. (*On Dislocations, &c.* p. 466.)

Fracture by which the epitrochlea alone is broken off, most commonly happens in children, in whom it may be an epiphysary disjunction, instead of a fracture, which takes place, since this process is ossified separately, and is not joined to the rest of the bone till towards adult age.

It may be caused by a fall or a blow on the part itself, or sometimes as some have supposed by the action of the muscles arising from it. These muscles after the fracture will also tend to displace the detached fragment downwards and forwards towards the forearm. The detached process may generally be felt, unless the swelling be very great, and on moving it crepitus will probably be obtained. The patient holds his arm semiflexed, and his hand pronated, and pain is produced in both these fractures if supination or extension is attempted.

The treatment of both these fractures of the internal condyle consists in applying a roller round the joint, to maintain the broken piece in apposition with the rest of the bone; in keeping the limb bent at a right angle, and supporting it in a sling. When the epitrochlea alone is broken off,

the hand should at the same time be pronated and the fingers flexed, in order that the muscles arising from the small detached fragment may be relaxed as completely as possible. In the more extensive fracture of the condyle, if there be much tendency to displacement backwards of the ulna, it may be advisable to apply splints in the way recommended for the fracture above the condyles.]

3. [*Fracture of the external condyle,* as of the internal, may involve a larger or smaller portion of the bone. The non-articular prominence (sometimes called epicondyle) may be broken off alone, or the fracture may extend into the elbow-joint, and detach more or less of the articular surface for the radius; or it may extend beyond it so as to include a portion of the trochlear surface of the internal condyle. Fracture of the non-articular portion alone, is not so likely to happen in the external as in the internal condyle, on account of its slighter projection. The arm is semiflexed, there is swelling on the outer side of the elbow; the movements of the joint are painful; crepitus is produced when the radius is rotated, and if the swelling be not very great the detached condyle may be felt. According to Sir A. Cooper, if the portion of the fractured condyle be large, it is drawn a little backwards and carries the radius with it, but if it be small, this circumstance does not occur. (*On Dislocations, &c.* p. 467.) M. Malgaigne has remarked, that simultaneously with this displacement backwards, the upper extremity of the detached fragment is sometimes tilted forwards; and also that sometimes it is separated in the lateral direction from the rest of the bone, so as to cause a sensible increase in the breadth of the elbow-joint. He considers this fracture to be one of the most frequent in the vicinity of the elbow. Desault speaks of one case in which he found the limb always retained in the supine position.

Treatment.—Sir A. Cooper recommends a roller round the joint, which will prevent lateral displacement, and afterwards the same rectangular splint used for the fracture above the condyles; (*On Dislocations, &c.* p. 468) or a rectangular splint may be applied laterally on the outer side of the arm and forearm. It will be well to retain the hand in the supine position, with the fingers not much flexed, so as to relax the supinators and extensors which take origin from the external condyle.

This fracture does not always unite by bone. Sir A. Cooper speaks of two cases in which the union was ligamentous; in one of them the fracture was intracapsular, only a small portion of the condyle being obliquely split off. M. Malgaigne also has met with cases of fibrous union, and he represents one in which a proper false joint had been formed surrounded by an external fibrous capsule. (*Traité des Fract. &c.* t. i. p. 558.)]

FRACTURES OF THE FOREARM.

The forearm is more frequently broken than the arm, because external force operates more directly upon it than upon the latter part, especially in falls on the hand, which are frequent accidents. The forearm is composed of two bones, the ulna and the radius. The last is much more liable to fractures than the first, because it is articulated with the hand by a large surface, and all the shocks received by the latter part are communicated to it. The situation of it also more

immediately exposes it to such causes as may break it. However, both the bones are frequently broken together. Bichat in his account of Desault's practice, mentions, that fractures of the forearm often held the first place in the comparative table of such cases kept at the Hôtel-Dieu, and other records point to the same conclusion.

Baron Dupuytren, states that in 1829, out of 109 fractures brought to the Hôtel-Dieu, 23 were of the forearm, 16 being of the radius, 5 of both bones, and 2 of the ulna. In 1830, in 97 fractures, 22 were of the forearm, 16 being of the radius alone, 4 of both bones, and 2 of the ulna.

[Mr. Lonsdale reports that out of 1901 fractures occurring during six years at the Middlesex Hospital, 386 were of the forearm; of these 93 were fractures of both bones, 197 of the radius alone; 64 of the ulna alone (its shaft); 30 of the olecranon; and 2 of the coronoid process. M. Malgaigne, out of 1024 fractures at the Hôtel-Dieu, found 305 of the forearm; of which 107 were of both bones; 160 of the radius; 29 of the shaft of the ulna; and 9 of the olecranon process. From all these records, it appears (if we exclude fractures of the olecranon, which in Mr. Lonsdale's table appear to be unusually numerous) that fractures of the radius alone are by far the most frequent, while fractures of both bones hold the second place, and fractures of the ulna the third.]

Fractures of both bones may occur at the extremities or middle of the forearm. They are most frequent in the middle third, somewhat less common below, and very rare at the upper part, where the numerous muscles, and the considerable thickness of the ulna, resist causes, which might otherwise occasion a fracture. These accidents may be produced by direct external violence; or indirectly by a fall on the palm of the hand. The former case is the more frequent; in the latter, the radius, from its more extensive connection with the hand, receives the greater part of the shock, and is usually the only bone broken.

[The two bones may be broken at the same, or at different levels. The first will always be the case in a fracture caused by direct violence; the second may happen when it is the result of a fall on the hand, in which case, the radius is first broken, and the force then tells upon the ulna, which in its turn gives way at its weakest point. When they are broken at different levels, M. Malgaigne has always found the radius broken above the ulna, and this is what might be expected from the relative strength of the two bones above and below.]

An incomplete fracture, or bending of the bones, is not unfrequently met with in children; indeed, this kind of injury is much more common in the forearm than in any other bones. M. Malgaigne believes that in these cases there is almost always a partial fracture, and not a mere bending of the bone, the fracture being situated on the side of the convexity of the curve and extending through a portion only of the thickness of the bone.]

Sometimes the bones are broken in more than one place; the fracture is, in fact, comminuted: Desault speaks of a patient over whose forearm a cart had passed, so as to break the bones, at their middle and lower part, into six distinct portions. The middle ones, notwithstanding they were quite detached, united very well, with hardly any deformity.

The symptoms indicating fractures of the forearm are not likely to lead the surgeon into any mistake; motion at a part of the limb, where it was previously inflexible; a crepitus, almost always easily felt; sometimes a distinct depression in the situation of the fracture; occasionally a projection of the ends of the fracture beneath the skin; pain on moving the part; a noise sometimes audible to the patient at the moment of the accident; an inability to perform the motions of pronation and supination; and an almost constantly half-bent state of the forearm.

[Displacement in the longitudinal direction seldom occasions the surgeon much trouble. It may take place to a slight extent when the fracture is oblique, but when it is transverse, the broken surfaces seldom become so completely clear from each other as to enable them to overlap. When it does occur, this displacement is to be ascribed rather to the cause of the fracture than to muscular contraction. An angular deformity, either forwards or backwards, may also be the result of the violence which causes the fracture; but the most important of all is the transverse displacement, in which the four pieces approach one another, and the interosseous space is diminished or entirely obliterated near the seat of fracture. This approximation is mainly due to the action of the pronator muscles; it is attended with an increase in the antero-posterior and a diminution in the transverse dimensions of the forearm; it may affect the two upper fragments only, the two lower maintaining their natural distance apart, or the converse of this may happen. Lastly, there may be displacement in the direction of rotation, caused by the upper and lower portions of the fracture not remaining in an equal state of pronation or supination.]

Fracture of both bones in the immediate vicinity of the wrist-joint are not very frequent, although fractures of the radius alone in this situation are, as will be presently seen, exceedingly common. It, however, is occasionally the result of a fall, probably more violent than usual, on the palm of the hand. The injury produced is a fracture, generally transverse, of both radius and ulna, close to the wrist-joint, or, in children, through the line of union of the epiphyses; the lower fragments are displaced directly backwards, and the superior consequently project in front. (See *R. W. Smith, On Fractures, &c.* p. 166.)

This accident is very liable to be mistaken for a dislocation of the carpus backwards on the forearm; but the fracture may be known by the crepitation, by its greater mobility, and greater facility of reduction; and also by the fact mentioned by Boyer, that the styloid processes are displaced backwards with the carpus, and will follow any movements imparted to the hand, while in dislocation the reverse of this is the case. Any dislocation of the wrist-joint is of extremely rare occurrence. (See *DISLOCATIONS.*)

Treatment.—In the reduction, and also in the subsequent treatment of a fracture of both bones, the forearm should be bent to a right angle with the arm, and the hand placed in a position between pronation and supination. For the reduction, an assistant should take hold of the patient's hand, and extend the fractured parts, while another assistant makes counter-extension by fixing the humerus. The surgeon's attention should be particularly directed to preserve the interosseous space;

for, if this be obliterated, the radius cannot rotate on the ulna, nor the motions of pronation or supination be executed; and this object may be obtained with certainty by applying compresses and splints in such a manner that the fleshy parts may be forced into, and confined in, the interosseous space.

Boyer first applied two longitudinal and graduated compresses on the anterior and posterior surfaces of the forearm. These he retained in their position by a bandage, and he then applied an anterior and posterior splint. Both compresses and splints extended from the elbow to the wrist. In general, the longitudinal compresses, used by Boyer, for preserving the interosseous space, are not resorted to in England; [but anterior and posterior splints only are applied, and retained in their position by a bandage or by straps and buckles. The effect of a compress may be obtained in a more simple manner, by having the splints more thickly padded at the centre than at the sides, or by using convex splints, as suggested by Mr. Amesbury. It is desirable also that the breadth of the splints should slightly exceed the breadth of the forearm, in order to prevent the bandage from exercising any lateral compression. For the same reason, it is better not to apply any bandages beneath the splints, as recommended by Boyer. The palmar splint should extend as far as the fingers, to support the hand and retain it in a line with the forearm; for, when both bones are fractured, if the hand be permitted to hang down, its weight may produce an angular deformity at the seat of fracture.] The splint, however, should not pass beyond the first joint of the fingers; for many patients, after having had their fingers kept, for several weeks, in a state of perfect extension, have been a very long time in becoming able to bend them again. The posterior splint need not pass beyond the wrist.

If the fracture be simple, and the contusion inconsiderable, the patient need not be confined to bed, but may walk about, with his arm in a sling.

[The above treatment, with the hand in a state of semi-pronation, is that most usually adopted, and is certainly the most convenient to the patient. Some surgeons, however, recommend that the forearm should be kept in the supine position during the treatment. Mr. Lonsdale advocates it on the ground that, by the usual method, the radius is likely to unite with its lower piece more pronated than the upper, and that the movement of supination is afterwards often imperfect in consequence. The splints in the ordinary method, according to Mr. Lonsdale, retain the lower portion of the radius securely in one position, but do not prevent the upper piece from rotating on its axis, and in most instances it does so rotate in the direction of supination under the influence of the biceps and the supinator radii brevis, more especially if the fracture be above the insertion of the pronator radii teres, for then the two first-named muscles are not contracted by any antagonist whatever. He thinks that the supine position will obviate this inconvenience by bringing the axis of the lower piece, which is so much more easily acted upon, into correspondence with that of the upper. Another argument for the supine position is mentioned by Mr. Lonsdale, and in this M. Malgaigne also concurs, namely, that by it the interosseous space is more easily preserved, and the

bones have not the same tendency to fall towards each other as when the radius is partly rotated across the ulna. M. Malgaigne recommends it, therefore, when there is any difficulty in maintaining the interosseous space, but in an ordinary case he thinks that the usual semi-prone position is less inconvenient and equally advantageous. (See *Lonsdale, On Fractures*, p. 123; and *Malgaigne*, vol. i. p. 591.)]

FRACTURES OF THE ULNA.

[It will be necessary to consider separately: 1. *Fractures of the olecranon*. 2. *Fractures of the coronoid process*. 3. *Fractures of the shaft of the ulna*.]

1. *Fracture of the olecranon process*. [This fracture is not very uncommon. It is almost always caused by external violence directly applied to the part by a blow or fall on the elbow; but in some rare instances it has been known to be produced by the violent action of the triceps muscle. The fracture may happen at its base, its centre, or its extremity; the second case is by far the most frequent. The division is usually transverse, but occasionally it is more or less oblique. M. Malgaigne has met with cases of fracture at the base of the process which extended obliquely downwards and backwards so as to include an inch and a half or more of the posterior surface of the ulna. Fractures of the summit of the olecranon are the most uncommon; in two cases mentioned by Malgaigne, they were the result of muscular action, which had torn off the surface of bone receiving the insertion of the triceps.]

With regard to symptoms, the contraction of the triceps, being no longer resisted by any connection with the ulna, draws upward the short fragment to which it adheres, so as to produce between it and the lower one a more or less evident interspace. This interspace is situated at the back of the joint; it will be increased by flexion of the forearm, and diminished by its extension. Another symptom is a difficulty or inability of the patient to extend his forearm, the necessary effect of the detachment of the triceps from the ulna. It appears from the dissections made by Sir Astley Cooper, that the extent of the separation depends upon the degree of laceration of the capsular ligament, and of that portion of the internal lateral ligament which proceeds from the side of the coronoid process to that of the olecranon. (*On Dislocations*, &c. p. 487.) [The periosteum covering this process is also considerably strengthened by aponeurotic fibres prolonged downwards from the insertion of the triceps tendon.]

It must be owing to the untorn state of these parts that sometimes no appreciable separation takes place, and that patients occasionally retain the power of extending the forearm, as is exemplified in the case reported by Mr. Earle, where, on the sixth day after the accident (and not before), this power was destroyed by a sudden flexion of the forearm. (*Practical Obs.* p. 147.) The forearm is constantly half bent, the biceps and brachialis having no antagonists. The olecranon is more or less drawn up above the condyles of the humerus, which latter parts, on the contrary, are naturally situated higher than the olecranon when the forearm is half bent. The upper piece of bone may be moved in every direction, without the ulna participating in the motion. Besides these symp-

toms, we must take into the account the considerable pain experienced, and the crepitus perceptible, when the fragment is approximated to the surface from which it is detached.

[Fracture of the base of the olecranon may be accompanied by a dislocation of the radius and ulna forwards on the condyles of the humerus. Cases of this kind are recorded by Malgaigne. (*Traité des Fractures*, &c. t. ii. p. 633.)

Treatment.—The indications are to push the retracted portion of the olecranon downwards, and to keep it in this position at the same time that the ulna is made to meet it, as it were, by extending the forearm.

When there is much swelling, Sir A. Cooper employs leeches and evaporating lotions for two or three days; but when not much violence has been done to the limb, he applies a bandage at once. He places the arm in a straight position, presses down the fragment until it touches the ulna, and, after putting a slip of linen along each side of the joint, puts a roller round the limb above and below the olecranon. By tying the slips of linen which pass under the rollers, these are drawn nearer together, and the fragment of the olecranon is thus kept as near as possible to the ulna. Lastly, a splint, well padded, is applied along the front of the arm, and secured with a bandage, which is frequently wetted with spirits of wine and water. (*On Dislocations*, &c. p. 490.)

Baron Dupuytren applied what is termed the uniting bandage, with a compress above the upper fragment, and an anterior splint. (See *Clin. Chir.* t. i. p. 328.)

According to Desault, however, the forearm should not be completely extended, as, when the pieces of bone touch at their back part, they leave a vacancy in front, which is apt to be followed by an irregular callus, prejudicial to the free motion of the elbow. Hence, it was his practice to put the arm between the half bent and the completely extended state, and to maintain this posture by means of a splint along the fore part of the arm. But, as position operates only on the lower part of the olecranon, the upper one requires to be brought near the former, and fixed there, which is doubtless the most difficult object to effect, because the triceps is continually resisting.

Desault used to adopt the following method:—The forearm being held in the above position, the surgeon is to begin applying a roller round the wrist, and to continue it as high as the elbow. The skin covering this part being wrinkled, in consequence of the extension of the limb, might insinuate itself between the ends of the fracture, and consequently it must now be pulled upward by an assistant. The surgeon is then to push the olecranon towards the ulna, and confine it in this situation with a turn of the roller, with which the joint is then to be covered, by applying it in the form of a figure of 8.

A strong splint, a little bent, just before the elbow, is next laid along the arm and forearm, and fixed by means of a roller. The limb is then to be evenly supported on a pillow.

Camper laid great stress upon the inutility of keeping the arm perfectly extended: he found patients recover sooner and better when the elbow was kept half bent, and the joint gently exercised at as early a period as possible. “Agglutinationem scilicet motiri non debet chirurgus, sed sublati tu-

more ac inflammatione quiete et remediis aptis, cubitum quotidie prudenter movere, ut unio per tricipitis tendinem, seu per concretionem membranosam formetur, et os ossi non admoveatur. Verbo quemadmodum C. Celsus in *Med.* lib. viii. c. 10, § 4, p. 537, de cubito fracto præcepit. Quod si ex summo cubito quid fractum sit, glutinare id vinciendo alienum est, fit enim brachium immobile, ac, si nihil aliud quam dolore occurrendum est, idem qui fuit ejus usus est.” (*Camper de Fracturâ Patellæ*, p. 66, Hagæ, 1789.) Mr. Earle is also an advocate for placing the limb in a slightly bent position. (*Pract. Obs.* p. 165.)

The cure of the fractured olecranon is seldom effected by the immediate reunion of its fragments; there generally remains a greater or lesser interspace between them, which is filled up by a ligamentous substance.

[The impossibility of maintaining the fragments in apposition is the only reason why this fracture is so seldom followed by bony union. In Sir A. Cooper's experiments on animals, transverse fractures of the olecranon were always followed by ligamentous union; but when he divided it in the longitudinal direction, osseous consolidation took place without difficulty. If, therefore, we could succeed in preventing the retraction of the broken piece, we might expect union by bone to take place in this as readily as in any other fracture.

Mr. Lonsdale says he is certain he has seen cases, where close apposition of the ends of the bone had been maintained, in which ossific union had been produced, or something very like it, for not the least motion has existed afterwards, and a distinct ridge of substance like bone has been felt opposite to the seat of fracture. He has not, however, had any opportunity of further verifying this statement by dissection. Sir A. Cooper has met with union by bone when the fracture has been situated very near to the shaft of the ulna. M. Malgaigne also represents in his atlas (pl. xxiv.) a drawing of an oblique fracture of the base of the olecranon united by bone, though with considerable deformity. This case was complicated with luxation of the bones of the forearm forwards. Ligamentous union may, however, undoubtedly be considered the rule, to which union by bone is a very rare exception; the case in which the exception is most likely to take place is when separation is prevented on account of the fibrous tissues connecting the olecranon with the rest of the bone remaining entire. Sir A. Cooper has observed that the arm is weakened in proportion to the length of the ligament; for if this be very long, extension of the arm is rendered difficult from the necessarily diminished power of the triceps muscle; and that when it is of considerable length, it is often incomplete, having an aperture, or sometimes several apertures, in it. In about a month the splint should be removed, and passive motion begun; but all attempts at movement must be made with the greatest gentleness, for if it be commenced too soon, there is danger of the ligament becoming lengthened and weakened, or even of its being entirely absorbed again. (*On Dislocations*, &c. p. 473.) On the other hand, if movement be too long delayed, there may be great difficulty in overcoming the stiffness of the elbow resulting from the continuance of the extended position.]

Ankylosis of the elbow-joint has been known to follow a fracture of the olecranon. I have seen

a case in which the upper fragment was ankylosed to the humerus.

On an average the olecranon becomes firmly united about the twenty-sixth day. (*Desault*.)

2. *Fractures of the coronoid process.*—These fractures are very rare. Two examples are noticed by Sir Astley Cooper: in one case seen by him several months after its occurrence, the ulna projected backwards whilst the arm was extended, but it could be drawn forwards, and the elbow bent without much difficulty, when the deformity disappeared. In the other instance, which was met with in the dissecting-room, the coronoid process which had been broken off was united by ligament, and so movable that, when the forearm was extended, the ulna glided backwards upon the condyles of the humerus. Sir Astley Cooper is of opinion that the case admits of no other mode of union: he recommends keeping the arm steadily in the bent position for three weeks. (*On Dislocations, &c.* p. 470.)

[Mr. Liston mentions a case of this fracture from muscular action, in which the injury arose in consequence of the patient, a boy of eight years, having hung for a long time from the top of a high wall, afraid to drop down. (*Pract. Surg.* 3rd ed, p. 77.) Two cases are recorded in Mr. Lonsdale's tables from the Middlesex Hospital, but he only speaks of having seen one, and in this the process was felt more prominent than natural when the arm was extended, but very little retraction was present. (*On Fractures*, p. 162.) M. Malgaigne records two others in which this process is presumed to have been fractured, and one which was met with by M. Velpeau in a dissection. (*Traité des Fractures*, vol. ii. p. 634.)]

3. *Fractures of the shaft of the ulna* are less frequent than those of the radius, and take place generally towards its lower extremity, where it is most slender and least covered. The fracture is almost always the result of a force acting immediately on the part fractured, as, for instance, when in a fall the internal side of the forearm strikes against a hard resisting body, or when the arm is raised to ward off a blow aimed at the head. The superior portion of the ulna is unable to move on account of its mode of connection with the humerus at the elbow; but the inferior piece may be displaced towards the radius, partly by the weight of the hand, partly by the action of the pronator quadratus muscle. This displacement is less considerable than in fractures of the radius, and is sometimes so slight that there is danger of the injury being overlooked. The nature of the case is in most instances easily ascertainable.

Treatment.—An assistant should make whatever little extension may be necessary, and should incline the hand to the radial side of the forearm, while the surgeon pushes the flesh between the two bones, and applies an anterior and posterior splint in the manner recommended for fracture of both bones. [Special care should be taken to support the hand in a line with the forearm, or even to direct it slightly towards the radial side, in order that its weight may not displace the lower fragment of the ulna and cause it to encroach on the interosseous space. For this purpose, besides fixing the hand securely to the anterior splint, a sling of pasteboard or leather to afford equal sup-

port to both forearm and hand will be found useful.]

FRACTURES OF THE RADIUS

Are the most frequent of those of the forearm, as proved by records noticed in the foregoing section. The radius being almost the sole support of the hand, and placed in the same line with the humerus, is, for both these reasons, more exposed to fractures than the ulna. These, whether transverse or oblique, near its middle part or extremities, may be caused by a fall or blow on the forearm, sometimes by a fall on the back of the hand (see *Dupuytren, Clin. Chir.* t. iv. p. 182—184), or, as happens in most cases, by a fall on the palm of the hand.

In fourteen examples of broken radius, referred to by Dupuytren, three were caused by falls upon the back of the hand, and eleven by falls upon the palm. These facts refute one of Cruveilhier's inferences that the radius cannot be fractured by a fall upon the back of the hand. (*Clin. Chir.* t. iv. p. 182.) When likely to fall, we extend the arm and let the hand come first to the ground, in which case the radius pressed between the hand on the ground, and the humerus, from which it receives the whole momentum of the body, is bent, and if the fall be sufficiently violent, broken either near its middle part, or which is more frequent, about an inch above its lower extremity. The right radius appears to be more frequently broken than the left, for in ninety-seven cases fifty-nine happened to the right arm. (See *Clin. Chir.* t. iv. p. 181.) [It will be convenient to speak separately of—1, fractures of the upper extremity; 2, fractures of the shaft; and 3, fractures of the lower extremity of the bone.]

1. *Fracture of the upper extremity of the radius.*—[Fractures of the head or neck of the bone are extremely rare, except as forming part of a comminuted fracture of the elbow-joint. Sir A. Cooper never met with a case of fracture of the neck of the radius, and he thinks, therefore, that there must be some mistake in the assertion formerly made that they are of frequent occurrence. (*On Dislocations, &c.* p. 476.) M. Malgaigne mentions two cases of fracture of the head of the radius, both of which were complicated with fracture of the coronoid process and dislocation backwards at the elbow, but has never seen an unequivocal fracture of the head or neck of the radius alone. (*Traité des Fractures, &c.* t. ii. p. 636.) Mr. South, however, has recently repeated the statement that fracture through the neck of the radius is not uncommon, and is liable to be confused with dislocation of the bone forwards on the external condyle, but he does not bring forward any facts to support this opinion. (See *Trans. of Chelius*, vol i. p. 558.) Such a fracture would probably be difficult to detect on account of this part of the bone being thickly covered with muscles; but Sir A. Cooper thinks that a crepitus would be produced by fixing the external condyle of the humerus and rotating the radius, probably also the shaft of the bone would be drawn forward by the action of the biceps muscle. The most appropriate treatment would be that which has been recommended for fracture of the external condyle.]

In all fractures of the bones of the forearm, and particularly in those which are near the head of the radius, a false ankylosis is to be apprehended,

and should be guarded against by moving the elbow gently and frequently when the consolidation is advanced to a certain point.

Fractures of the forearm always require the part to be kept quietly in a sling.

2. [*Fracture of the shaft of the radius* may happen at any point from direct violence, or somewhere near the centre from a fall on the palm of the hand, though this latter cause most frequently produces a fracture near the lower extremity of the bone. Fractures of the shaft of the radius are probably not more frequent, as M. Malgaigne observes, than those of the shaft of the ulna, the excess in the proportion of injuries to the former bone being caused by the frequency of fracture at its lower extremity.]

When, after an accident of the kind above mentioned, pain and difficulty of performing the motions of pronation and supination supervene, the probability of a fracture of the radius is very strong. The truth is fully ascertained by pressing with the fingers along the external side of the forearm; also in endeavouring to perform supination or pronation of the hand, a crepitus and a motion of the broken portions will be perceived. When the fracture takes place in the upper third of the radius, the diagnosis is more difficult on account of the depth of soft parts over that part of the bone. In this case the thumb is to be placed under the external condyle of the os humeri, and on the superior extremity of the radius, and at the same time the hand is to be brought into the prone and supine positions. If in these trials, which are always painful, the head of the radius rests motionless, there can be no doubt of the bone being fractured. The ulna serves as a splint in fractures of the radius, and the more effectually as the two bones are connected with one another throughout their whole length. [Shortening, therefore, is impossible, unless the ulna be at the same time dislocated, and if there is any displacement it must be in the direction either of the diameter or of the circumference of the bone. The pronator muscles will tend to draw the bone inwards towards the ulna, and so to diminish the interosseous space; if the fracture be below the pronator teres, this muscle will influence the upper piece and the pronator quadratus the lower, but if the bone be broken above the point mentioned, both pronators will act on the lower piece, while the upper piece will be supinated by the supinator brevis and biceps, the latter muscle flexing or drawing it forwards at the same time that it assists in the supination. Such a displacement would implicate the bone both as regards its diameter and its circumference, and both these points should be well understood, as they require to be carefully attended to in the treatment. In this, however, as in most other fractures, the original violence may modify or even supersede muscular action, and produce a displacement of one or both fragments either backwards, forwards, or laterally.]

Treatment.—In general, when the radius alone is fractured, no extension is requisite. Splints padded in the same way as for the fracture of both bones, should be applied on the anterior and posterior surfaces of the forearm, the same care being taken to press outwards the ends of the fracture and to preserve the interosseous space, the only difference being that the hand should not be kept in a line with the forearm, but should be inclined

towards the ulnar side, that it may act upon the lower portion of the fracture so as to draw it outwards away from the ulna. During the treatment the elbow is to be bent, and the hand put in the mid-state between pronation and supination; that is to say, the palm of the hand is to face the patient's breast.

[Mr. Lonsdale recommends the supine instead of the semiprone positions in these fractures, for the same reasons as in the fractures of both bones, and which have been already stated. (*Ante*, p. 725.)]

3. *Fracture of the inferior extremity of the radius.*—[This, although it is one of the most frequent of all fractures, was not well understood till within a comparatively recent period, but was very generally confounded with dislocation of the wrist. Mr. Colles of Dublin, in 1814, was the first to give an accurate description of the injury. (See *Ed. Med. and Surg. Journal*, vol. x. p. 182.) Somewhat singularly, however, this memoir of Mr. Colles has not been much noticed by subsequent writers, and was not alluded to in former editions of this Dictionary, though the accident is often familiarly spoken of as Colles' fracture of the radius. Dupuytren in 1820, and subsequently, paid great attention to the subject, and strongly insisted on the frequency of fracture, and the almost impossible occurrence of dislocation of the wrist. This accident is almost constantly caused by a fall on the palm of the hand. The direction of the fracture, was stated by Dupuytren to be in general, oblique from above downwards, and from the dorsal to the palmar surface. (See *Clin. Chir.* t. iv. p. 183.) Subsequent investigations have, however, shown that it is more commonly transverse, although the obliquity when present, most frequently takes the direction just mentioned. Its situation is from half an inch to an inch above the inferior extremity of the bone; seldom so much as an inch and a half, as stated by Mr. Colles, who had not at that period had any opportunity of making post-mortem examinations of the injury. This is in reality the weakest part of the bone, notwithstanding its greater bulk, for it is composed entirely of light cancellated texture, only covered on the surface by an extremely thin layer of compact bone.]

The consecutive displacement will have a greater resemblance to a dislocation, the nearer the fracture is to the wrist. Fractures of the lower end of the radius seem to occur at all ages; for, in 14 examples, alluded to by Dupuytren, the ages of the patients varied between 8 and 88; but, in young subjects, a separation of the epiphysis is more likely to occur than a fracture. Occasionally the lower fragment is split vertically in two or more pieces. In a few rare cases, besides a fracture of the radius, the ulna is dislocated, and projects through the skin. (*Dupuytren*, vol. cit. p. 190.)

[Fracture of the styloid process of the ulna is a not unfrequent complication.]

The direction in which the force is applied, when a person falls on the palm of the hand, causes the upper portion of the radius to be displaced forwards, and the lower fragment with the carpus to project backwards, producing the appearances thus described by Mr. Colles:—"The posterior surface of the limb presents a considerable deformity, for a depression is seen in the forearm, about an inch and a half above the end of the

bone ; whilst a considerable swelling occupies the wrist and metacarpus ; indeed the carpus and base of the metacarpus appear to be thrown backwards so much, as, on first view, to excite a suspicion that the radius has been dislocated forward. On viewing the anterior surface of the limb we observe a considerable fulness, as if caused by the flexor tendons being thrown forwards ; this fulness extends upwards to about one third of the length of the forearm, and terminates below at the upper edge of the annular ligament of the wrist. The extremity of the ulna is seen projecting towards the palm and inner edge of the limb ; the degree, however, in which this projection takes place is different in different instances. (See *Ed. Med. and Surg. Journal*, 1814, vol. x. p. 183.)

This description however, though so far perfectly correct, does not comprise quite the whole of the truth ; and Dupuytren appears to have been the first to notice that the lower fragment of the radius undergoes at the same time a further alteration in its position, by which its articular surface is directed outwards and the hand is placed in a position of abduction. On this point Mr. R. W. Smith observes that "the lower fragment of the radius along with the carpus, besides being displaced backwards, is also drawn towards the side of supination, and this two-fold displacement causes the wrist to assume a singularly twisted appearance, such as might be supposed to result, were it possible to supinate the hand and wrist, the forearm being at the time fixed in a state of pronation. Dupuytren and others have described the hand as being in a state of abduction, but this statement is not strictly correct, for the hand is displaced outwards along with the carpus and lower fragment of the radius 'par un mouvement de totalité.' " (*On Fractures, &c.* p. 139.) Mr. Smith's own description, however, of what takes place, would seem to show that Dupuytren was right in calling it a movement of abduction, rather than as Mr. Smith here declares, a "*mouvement de totalité*" of the hand and lower fragment of the radius. The following extract from the latter gentleman's work will render this more apparent:—"This double displacement is the result of the action of the supinator longus upon the one part, and of the long extensors of the thumb upon the other; the latter draw the lower fragment of the radius, with the carpus, towards the side of extension, thus directing the articular surface of the radius upwards (?) and backwards, while the former muscle, viz. the supinator longus, besides supinating the lower fragment, also elevates the styloid process, giving the carpal surface an inclination outwards,"—and also that "as long as the inferior radio ulnar ligaments remain unbroken" (which he believes to be most frequently the case) "and the lower end of the ulna entire, it is obvious that the inferior fragment of the radius must be displaced *obliquely*; that, in fact, the styloid process when being drawn upwards and backwards, must move through a portion of the circumference of a circle, and thus the upper end of the lower fragment is thrown towards the ulna." (p. 141.)

The pronator quadratus acts almost exclusively on the upper fragment, and draws it towards the ulna ; this displacement, however, is inconsiderable, on account of the small extent of the interosseous space at this level. The forearm is in

consequence but slightly, if at all, diminished in its transverse diameter at the seat of fracture ; but its antero-posterior dimensions are very perceptibly increased. The patient has lost all power over the movements of pronation and supination, and generally supports the injured part on the palm of the opposite hand. From the firm way in which the fragments are locked together, there may be considerable difficulty in eliciting a crepitus, and the head of the radius may even be felt to move when the hand is rotated ; the surgeon should therefore first employ a degree of extension sufficient to restore the fragments to their proper relative position, and then, on rotating the hand, the grating of the broken surfaces will usually be felt, and the head of the radius will be found to remain motionless. (*R. W. Smith*, loc. cit. p. 138.)

M. Voillemier believes that these fractures are almost always attended with impaction or penetration of the fragments, and that the compact tissue of the upper portion, by the continuance of the force after the fracture has taken place, is driven into the cancellated tissue of the lower fragment. He describes several varieties in the way in which this penetration may take place, but thinks that in most cases it extends to a greater depth posteriorly than anteriorly and externally than internally, thus giving rise to the double deformity at the seat of fracture, which has been already described. This author also thinks that the circumstance of impaction may explain the difficulty of detecting crepitus which is so often met with in these cases. (See *Archives Gén. de Méd.* vol. xiii. 1842, p. 261.) Mr. Smith, however, differs from M. Voillemier respecting the occurrence of impaction, and offers a different explanation of the appearances adduced by the French surgeon in support of his theory. This difference of opinion has, no doubt, arisen from the fact that opportunities of examining this fracture in a recent condition are very seldom met with. Both statements are probably too exclusive, and the truth will no doubt be found to be, that the fracture is sometimes attended with impaction and sometimes not. Mr. Smith, after stating the arguments against the occurrence of impaction, says, "he thinks that as long as the ulna remains unbroken, and the ligamentous connections between the two bones uninjured, it is scarcely possible for either fragment to penetrate the other, even to the extent of half an inch." (p. 159.) Probably this is very nearly as much as M. Voillemier would himself contend for. The subject is fully discussed in Mr. Smith's admirable treatises on fractures and dislocations, and M. Voillemier's essay, above referred to, is also well worth an attentive perusal.

The remarks hitherto made refer exclusively to the fracture caused by a fall on the palm, but the lower extremity of the radius is occasionally, though rarely, broken by a fall on the back of the hand. Out of fourteen cases of fractured radius, seen at the Hôtel-Dieu, in 1830, Dupuytren found three from this cause ; but this must be considered as an unusually large proportion. The characteristics of the injury are in this case reversed ; the upper portion of the radius projects backwards, and the lower portion with the carpus is thrown forwards towards the palm ; the lower end of the ulna is prominent at the posterior and inner part of the wrist. Both kinds of fracture might be mistaken for dislocation, the former most

resembling a dislocation backwards, the latter a dislocation forwards, of the carpus. Besides the usual signs, however, such as crepitus, increased mobility, &c. the fracture may be known by the altered position of the styloid process, with reference to the shaft of the radius, and by its following any movement communicated to the hand; and also by the oblique or twisted appearance of the deformity in both varieties of fracture of the radius singly, which does not belong to a dislocation, since both bones are then displaced together, either in one direction or the other. For this reason the mistake is not so likely to be made in the fracture of the radius alone as when the lower end of the ulna is also broken. (See FRACTURE OF BOTH BONES.) The surgeon should always bear in mind the frequency of fracture of the lower end of the radius, and the extreme rarity of dislocation of the wrist. (See DISLOCATION.)

Treatment.—In the treatment of the ordinary fracture of the lower extremity of the radius, after the deformity has been reduced by a suitable degree of extension and counter-extension, special attention is required to prevent any recurrence of the displacement of the lower fragment; first, in the direction backwards; secondly, in the direction outwards or towards the side of supination. Mr. Colles, aware of the necessity of fulfilling the first of these indications, used anterior and posterior splints, with a thick compress beneath the anterior splint opposite the seat of fracture, to press the lower end of the shaft of the bone backwards. He also used a third narrow splint on the ulnar side to press the extremity of this bone against the side of the radius.

Dupuytren employed anterior and posterior splints in the ordinary way, with a third on the inner side, so contrived as to counteract the abduction of the hand. This ulnar splint was composed of a steel plate covered with leather, about fifteen inches long and an inch and a quarter wide; it consisted of a straight portion corresponding to the ulna, and a part curved downwards corresponding to the hand. The hand was bound to this curved portion, and by that means securely maintained in the position of adduction. This plan effectually fulfilled the second indication; but it must have been insufficient as regards the first, as no compresses appear to have been used under the splints to prevent displacement backwards.

Sir A. Cooper used an anterior and posterior splint with a compress posteriorly on the lower fragment of the radius, and another internally to press upon the ulna. Following the plan recommended by Mr. Cline, the splints, which reached to the extremities of the metacarpal bones, were not bandaged lower than the wrist, and the hand was allowed to hang between them unsupported, so that by its weight it should draw upon the radius in the direction of adduction. The sling which supported the forearm was for this reason not permitted to extend beyond the wrist.

M. Malgaigne uses anterior and posterior splints with compresses to prevent the displacement backwards, and two lateral splints also with compresses beneath them, one so placed as to press inwards the lower fragment of the radius, the other to press outwards the lower extremity of the ulna. He thinks the splints should not extend beyond the first row of carpal bones, and that there is no object in confining the hand if the lower extremity of

the radius is securely fixed, but that on the contrary it is much better to leave it free, that there may be less risk of permanent stiffness of the wrist and fingers.

The following plan, recommended by Mr. R. W. Smith, seems calculated to fulfil very completely all the required indications. "The hand being moderately adducted, a cushion is to be placed on the posterior surface of the limb, of sufficient length to extend from the elbow to the fingers; the portion of this cushion which corresponds to the lower fragment of the radius and to the carpus, should be thicker than any other part, and from its ulnar to its radial border should gradually increase in thickness. A transverse section of this portion of the cushion would represent an isosceles triangle, the base of which would correspond to the radial border of the limb. The objects proposed to be attained by constructing the pad of this form are, to press the lower fragment of the radius forwards, and to direct its external border towards the side of pronation. A second cushion, thicker below than above, is to be placed upon the front of the limb, but should not descend below the lower margin of the superior fragment, for otherwise it would, to a certain extent, counteract the influence of the dorsal cushion, and would tend to maintain the displacement backwards of the inferior fragment. An anterior and a posterior splint are then applied, each of which should be at least an inch broader than the forearm; the posterior should extend from the elbow to the fingers, and should be curved from the wrist downwards, to receive the adducted hand; the anterior need not descend below the palm of the hand: a roller is then to be carried round the splints in the ordinary manner.

By constructing and placing the cushions in the manner above described, the two fragments are pressed in opposite directions, and the carpal surface of the inferior fragment is directed forwards, while the curved splint, by maintaining the hand moderately adducted, tends to restore to the articulating surface its natural direction inwards, quite as effectually as the ulnar splint of Dupuytren, and with much less uneasiness to the patient. It is scarcely necessary to mention that the form recommended can be readily given to that portion of the dorsal cushion which corresponds to the lower fragment, by the employment of graduated compresses. The apparatus recommended by Nélaton is very similar to that just described, and is identical with it in principle; the use of the curved dorsal splint, instead of the ulnar splint of Dupuytren, constitutes the only difference of importance. (*On Fractures*, &c. p. 167.) Instead of the ulnar splint, M. Nélaton has since used a dorsal splint, curved at its lower end in the shape of the handle of a pistol, and very similar therefore to that recommended by Mr. Smith.

The splints should be retained for three weeks in young persons, and for four or five in the aged, before passive motion is attempted. The recovery in these cases is slow, and six months will sometimes elapse before the motion of the fingers is completely restored. (See A. Cooper, *On Dislocations*, &c. p. 496.)

In the fracture with displacement of the lower fragment forwards, the same principles of treatment will apply; but the position of the pads used to press the ends of the fracture into position, must of course be reversed.]

FRACTURES OF THE CARPAL AND METACARPAL BONES, AND PHALANGES OF THE FINGERS.

The bones of the carpus, when broken, are usually crushed, as it were, between very heavy bodies, or the limb has been entangled in powerful machinery, or suffered gunshot violence. It must be obvious, therefore, that, as the soft parts are also seriously injured, these cases are generally followed by severe and troublesome symptoms, and sometimes require the performance of amputation, either immediately or subsequently. When an attempt is to be made to save the part, the chief indications are to extract loose pieces of bone, and prevent inflammation, abscesses, and mortification. The parts may at first be kept wet with a cold evaporating lotion, any wound present being lightly and superficially dressed; but, afterwards, as soon as all tendency to bleeding is over, emollient poultices may be applied over the dressings instead of the lotion. Should abscesses form, early openings should be practised, so as to prevent the matter from extending up the forearm.

Fracture of a *metacarpal bone* may be produced by direct or indirect violence. Fractures caused by striking a blow with the closed fist, or by a fall on the closed hand, are examples of the latter kind. In this case, the third metacarpal bone, from its greater length, is most likely to suffer; but in a fracture from direct violence, those of the little finger and thumb are more frequently broken than the other three, though, in most cases, unless the force has operated by a very limited surface, more than one metacarpal bone is fractured. The fracture may be simple or compound; if from direct violence, it is most commonly the latter, and the soft parts are wounded and lacerated by the same violence which has injured the bone. [The upper piece, from its mode of connection with the carpus, is nearly immovable, but the lower fragment may be displaced either towards the dorsal or palmar surface. Most frequently, according to Malgaigne, its fractured extremity forms an angular projection posteriorly, and the head of the bone in consequence is prominent towards the palm.]

According to Sir A. Cooper, the head of a metacarpal bone is sometimes broken off, and gives the appearance of dislocation of the finger, as the head of the bone sinks towards the palm of the hand. In the treatment of this case, a large ball is to be placed in the hand, and to be grasped by it, and the hand is to be bound over it by a roller; and thus the depressed extremity of the bone is raised to its natural situation. (*On Dislocations*, p. 506.) The same plan is also recommended for fractures of other parts of the metacarpal bones, but care must be taken lest it increase the tendency to project backwards already alluded to: this evil may be avoided by making the pressure operate upon the head of the metacarpal bone, and not opposite the seat of fracture. If there is no displacement a piece of pasteboard or gutta percha moulded to the hand will be found to answer every purpose. There is no necessity to include the ends of the fingers, and it is better that they should not be kept permanently extended.

In a compound or comminuted fracture, the hand and forearm should be kept at rest on a splint, and treated according to the suggestions above given for fracture of the carpus. In some cases, of course,

when the hand is badly crushed, amputation becomes necessary.

Fractures of the phalanges of the fingers are almost always produced by direct violence, and are therefore very frequently compound or comminuted—force applied indirectly is more likely to cause a dislocation than a fracture. In compound fractures of the extreme phalanges, if the soft parts are much injured, it is better to amputate at once, but in the first or second phalanges an attempt should always be made to save the finger, unless the parts are so much injured as to preclude all chance of success. In a simple fracture, the finger should be placed on a small wooden splint; or a piece of wetted pasteboard may be moulded to the part; but in compound fractures, and especially when several fingers are injured, it is better to confine the whole hand on a splint, and to keep the part at rest in a sling.]

FRACTURES OF THE SACRUM.

The sacrum is less frequently broken than the other bones of the pelvis; a fact attributable to its thickness, its spongy texture, and the advantageous way in which it supports the weight and efforts of the whole trunk. For the sacrum to be broken, the violence must be exceedingly great, like that resulting from the fall of a very heavy body, or the passage of a carriage wheel over the convex side of the bone, or a fall from a great height on that part. Fractures of the sacrum, when they do happen, are generally accidents of a most dangerous kind, because, in addition to other injuries, with which they, in common with all fractures of the pelvis, are liable to be complicated, great damage may be done to the sacral nerves. Hence, retention of urine, inability to retain this fluid, involuntary discharge of the fæces, paralysis of the lower extremities, &c. Another principal danger also depends upon the injury which the pelvic viscera may have suffered from the same violence which broke the bone.

When the fracture is situated at the upper part of the sacrum, which seldom happens on account of the thickness of the bone in that situation, there is no displacement unless the bone is smashed, and the fragments are driven inwards by the same force which produced the fracture; a case which always implies severe injury of the external and internal soft parts. But when the fracture is transverse, and occupies the lower portion of the bone, where it is less thick, the inferior fragment may be displaced forwards, towards the rectum. In general, fractures of the higher part of the bone are not easily detected. (See *Boyer, Mal. Chir.* t. iii. p. 152.)

[The displacement, according to Malgaigne, is usually such that the inferior fragment remains in contact with the other by its base, but is inclined more or less forward at its apex. The coccyx of course shares in the displacement of the lower portion of the sacrum, and may project forwards sufficiently to cause an obstruction at the lower part of the rectum. (*Traité des Fractures*, t. i. p. 636.) These fractures generally take a transverse direction; there is, however, a specimen of vertical fracture of the sacrum in the Museum of the College of Surgeons.]

If the nature of the injury is doubtful, the finger should be introduced into the rectum, when if there is a fracture, an unusual mobility of the

coccyx and lower part of the sacrum will probably be felt, and if there is displacement forwards of the lower fragment the finger may be used to press it back into its proper situation.]

When the violence has been such as to make it probable that it has extended its effects to the pelvic viscera, every means in the power of art must be adopted to prevent and allay inflammation. Leeches should be applied to the vicinity of the sacrum, and bleeding from the arm should, if it appears necessary, be practised. Any difficulty, either in the expulsion or retention of the urine and faeces, will likewise claim immediate and constant attention. (See URINE, *Retention of, Incontinence of, &c.*) With regard to the particular means for promoting the union of the fractured sacrum, quietude is the most important; and is in most cases the only treatment necessary.

[If, however, the lower fragment should project forwards to a painful extent, and appear likely to produce inconvenience, and if, after it has been reduced by the finger in the rectum, the displacement should recur, it might be advisable to apply permanent pressure from within by means of some substance, such as a pessary, introduced into the rectum. Treatment on this principle has been practised in France in two cases, by MM. Judes and Bemond, and with sufficient success to afford encouragement for further trial, should the exigencies of the case seem to require it. (See *Malgaigne*, op. cit. p. 638.) Mild laxative medicines, or enemata, should be given to render the action of the bowels as gentle and free from irritation as possible.]

FRACTURES OF THE OS COCCYGIS.

Though much slighter than the sacrum, it is less frequently broken, because less exposed to external force, and capable of a degree of motion, by which it eludes the effects of violence. But, in elderly persons, in whom the different pieces are connected by ankylosis, a fall on the buttock, or a kick, may fracture this bone. The accident is known by the movableness of the fragments, and the acute pain produced when the thighs are moved, and the act of defæcation, the fragments being then disturbed by the action of the external sphincter, gluteus maximus, and coccygeus.

The treatment of fractures of the coccyx consists in enjoining quietude. If the lower portion of the bone project forwards it may be replaced by the finger introduced into the rectum, but all attempts of this kind should be made with great gentleness, as the soft parts are not in a state to bear much handling without ill effects. The patient should avoid walking about, as this would put the gluteus maximus muscle into action, and disturb the broken bone. He should refrain from lying upon his back, or placing himself in a sitting position.

[The recovery from this accident is sometimes very tedious. Mr. South mentions two cases, in both of which it occupied a period of nearly two years. Great relief was obtained, and a cure at last effected, by constantly wearing a pair of thick oblong pads on the ischial tuberosities, so that the coccyx was protected from all possibility of pressure in the sitting position. (See *Translation of Chelius*, note, p. 543, vol. i.)]

FRACTURES OF THE OSSA INNOMINATA

Are generally produced by the passage of the

wheels of heavy carriages over the pelvis, falls from great heights, the kicks of horses, &c., and are always attended with considerable contusion of the soft parts, and sometimes with great injury of the pelvic viscera. The anterior superior spinous process of the ilium is sometimes broken off by the kick of a horse. I have seen several examples of fracture of the pelvis by gunshot, some of which were accompanied by injury of the bladder or rectum.

The two ossa innominata may be broken together; but commonly only one of them is thus injured. Most frequently the fracture takes place in the upper expanded portion of the bone, known under the name of the ilium, though sometimes it happens either in the ischium, or the os pubis. The solution of continuity may be limited to one part of the bone, or extend to several parts of it; and there may be a greater or lesser number of fragments, and these attended, or not, with displacement. In many instances, in which the pelvis has been violently jammed between two bodies, or run over by a heavy carriage, the bones of the pelvis, besides being fractured, are dislocated, some interesting examples of which accident are recorded by Sir A. Cooper. (*Surgical Essays*, part i. p. 49, &c.)

Fractures of the ossa innominata are unavoidably attended with more or less contusion of the soft parts; and when the violence has been very great, the pelvic viscera may be seriously bruised, crushed, or lacerated, and the large nerves contained in the pelvis, or the spinal marrow itself, injured: hence, extravasation of blood or urine in the cellular tissue of the pelvis; ecchymosis deeply situated; injury of the kidneys; complete loss of motion; paralysis of the lower extremities; discharge of blood, or a black bilious matter, by vomiting or stool, either immediately or at more or less distant periods from that of the accident; retention of urine; fever; painful tension of the abdomen from inflammation of the peritoneum and bowels; the formation of abscesses, which are sometimes of great extent; sloughing; and death. (*Boyer, Mal. Chir.* t. iii. p. 154.)

As the same author has observed, the violence, occasioning a fracture of the ossa innominata, may produce a displacement of the fragments, and carry them more or less away from their natural situation. When the os pubis, or ischium, is broken, the splinters may be propelled into the urethra, or even through the bladder, and give rise to extravasation of urine; or by merely compressing these organs, they may cause more or less interruption of their functions. But, unless the fragments be displaced by the same force which caused the fracture, they can hardly be drawn out of their place by any other circumstance, since they are retained by the muscles attached to both fragments, and by surrounding ligamentous expansions.

Owing to the deep situation of fractures of the pelvis, and to there being generally no displacement nor mobility of the fragments, the diagnosis is sometimes attended with difficulty. A suspicion of the accident may be entertained when the pelvis has suffered considerable violence, the patient experiences great agony, and all motion of the trunk and lower extremities is difficult and painful. If the fracture should be in the ilium, especially its upper and front portion, or in the os pubis, the

mobility of the fragments, or even a crepitus, may be distinguished in a thin subject, if, when he is lying horizontally, with his thighs and legs bent, and his head and chest elevated, the projecting part of the os innominatum be taken hold of, and an attempt be made to move the fragments in opposite directions.

When the fracture is of a part of the os innominatum very deeply placed, and is limited to a single point of the os pubis, or ischium, so that no detached movable fragment has been produced, the exact nature of the case can rarely be made out with certainty, before the patient's death, and the dissection of the parts.

Fractures of the ossa innominata are accompanied with serious danger. When the fragments are displaced, and do not admit of being rectified again, the disorder arising from this cause may have fatal consequences. And, as Boyer observes, even when such displacement does not exist, these fractures are not the less to be apprehended, on account of the injury which the spinal marrow and the nerves, vessels, muscles, and viscera within the pelvis are likely to have sustained. These complications, which are exceedingly frequent, may prove directly fatal, or destroy the patient at a period more or less remote from the time of the accident. One terrible accident of this kind, which happened close to my house at Shepperton, proved fatal in half an hour.

When the pelvic viscera and urethra have escaped injury, a cure of the fracture may be effected by means of rest; a position in which all the chief muscles attached to the pelvis are relaxed; and a roller or T bandage. (*Boyer, Mal. Chir. t. iii. p. 156.*) Or the patient may be placed on a double inclined bed; a broad leather bandage may be passed round the pelvis, and buckled firmly in front of it, and the feet secured to the foot-board. (*Earle.*) The grand indication is to obviate the consequences of inflammation of the parts within the pelvis, and even of the peritoneum and abdominal viscera, by copious and repeated blood-letting. Any complaints respecting the evacuation of the urine and feces must also receive immediate attention. When there is great contusion, and the bones are badly broken, the patient cannot move nor go to stool without suffering the most excruciating pain. To afford some assistance in such circumstances. Boyer, in a particular case, passed a piece of strong girth web under the pelvis, and collecting the corners into one, fastened them to a pulley suspended from the top of the bed. This enabled the patient to raise himself with very little effort, so that a flat vessel could be placed under him. In these and other cases, particularly compound fractures and paralytic affections from diseased vertebræ, the use of a bed constructed on the principles suggested by the late Sir James Earle, is of great service. (*See Obs. on Fractures of the Lower Limbs; to which is added, an Account of a Contrivance to administer Cleanliness and Comfort to the bed-ridden. 1807.*) Mr. Earle has also exerted his mechanical ingenuity with great success in the invention of a bed, admirably well calculated for the treatment of fractures, and other cases, in which it is an object of high importance to enable the patient to empty the bowels, without changing his position.

Sometimes, notwithstanding the rigorous adoption of antiphlogistic measures, abscesses cannot

be prevented from forming in the pelvis, particularly when there are detached splinters driven inwards. These collections of matter should be opened as soon as a distinct fluctuation can be felt. The splinters may wound the urethra or bladder, and cause an extravasation of urine. Desault extracted a splinter, which had had this effect, from the bottom of a wound made for the discharge of the effused urine. In these cases a catheter should be employed without delay, and kept introduced in order to prevent the urine from collecting in the bladder, and afterwards insinuating itself into the cellular tissue of the pelvis, or even into the cavity of the abdomen. (*Chopart.*) In University College Museum is a specimen of a fracture of the pelvis, which runs through the rami of the ischium and os pubis. The injury caused retention of urine and laceration of the urethra by one of the fragments, followed by fatal extravasation of urine. An interesting case of fracture of the ossa innominata, attended with rupture of the bladder, and followed by fatal peritonitis, has been recorded by Cloquet. (*Nouveau Journ. de Médecine, Mars 1820.*) The ossa pubis were forced half an inch from each other. The horizontal branch of the os pubis, and the ascending ramus of the ischium, were broken; the sacrum was dislocated from the ossa ilii, and driven forwards within the cavity of the pelvis. The right sacro-iliac symphysis was broken only at its fore part, and its bones still retained their connection. Vast quantities of blood were found extravasated in the lumbar region and about the pudenda. As soon as the abdomen was opened, three pints of a yellowish fluid, having a urinary smell, immediately gushed out. In this case catheters of various sizes were introduced, even a syringe adapted to them was used, but nothing could be thus drawn off but a few drops of blood.

[The bottom of the acetabulum may be fractured, and the head of the thigh bone driven into the cavity of the pelvis. Sir A. Cooper mentions a case of this kind, the symptoms of which are stated to have resembled those of a dislocation into the sciatic notch. The patient died four days afterwards. (*On Dislocation, &c. p. 114.*) In three or four examples, Dupuytren found the acetabulum fractured and forced inwards by the head of the femur, by a fall on the feet or knees. In the most remarkable of these cases, the uninjured head of the thigh bone had passed entirely into the pelvis; and the neck, which was free from fracture, was so firmly wedged in the opening, that the reduction of this new species of dislocation was exceedingly difficult, even in the dead subject. In children, force, directed against the bottom of the acetabulum, may disjoin the pieces of the os innominatum combining to form it. (*See Dupuytren, Clin. Chir. t. ii. p. 110.*) Mr. C. H. Moore has recorded a remarkable case of injury of the pelvis, in which the acetabulum of the left side had been broken into three pieces, corresponding with the primary divisions of the bone, and the head of the femur had passed into the pelvic cavity. There was also fracture of the rami of the pubes and ischium on the opposite side. This patient lived for several years and was able to walk without any very serious lameness. It was found after death that the pelvis had become greatly distorted, but no union had taken place, though there was

copious deposit of bone in the neighbourhood of the fracture. (See *Med. Chir. Trans.* vol. xxxi. p. 107.)

In some well marked cases of fracture of the os innominatum, extending into the acetabulum, Mr. Earle found that the symptoms nearly resembled those of fracture of the neck of the femur. Thus, in one example of fracture of the acetabulum in two directions, with an extensive comminuted fracture of the ilium, with some displacement, and a fracture of the os pubis in three places, the patient "had lost all control over the left lower extremity, and could not raise it from the bed. There was no visible shortening of the limb, but the foot was everted. Any attempt to rotate the limb caused great pain, and was accompanied with a very sensible crepitus when the hand was applied over the hip-joint." The trochanter on the injured side was not nearly so prominent as on the sound one, and almost on a level with the anterior superior spinous process of the ilium. The patient recovered from these severe injuries, and after a time died of disease in the chest. The reparation of the fractures was complete.

[In a second case symptoms were observed as nearly as possible similar to the above. Both resembled fracture of the neck of the femur in the loss of power over the limb, the eversion and crepitus, but differed from it in the absence of shortening and in the freedom of motion, especially of abduction, which is always attended with severe pain in fracture of the neck of the femur. (See *Med. Chir. Trans.* vol. xix. p. 249.)]

In University College Museum is a preparation also exemplifying a recovery from an equally severe fracture of the pelvis, implicating the ilium, ramus of the left ischium, and the sacrum. The fractures are all united. In this instance also the loss of prominence of the trochanter, and the freedom of motion of the joint, particularly of abduction, were the most marked symptoms.

[Another instance of this kind, which also survived several years, was observed by M. Morel-Lavallée. This case was treated for fractured neck of the femur, but after death it was found that the acetabulum had been fractured, and that the head of the thigh bone had sunk more than an inch into the pelvis. The fracture was irregularly consolidated. (See *Malgaigne, Traité des Fractures*, vol. ii. p. 881.)

The margin of the acetabulum is sometimes broken off, usually at the upper or posterior part, and if the detached portion be sufficiently large, it may permit a partial dislocation of the head of the femur. Some of the cases of this kind which have been noticed have been in fact dislocations of the hip, complicated with a fracture of the acetabulum; in others, however, the dislocation seems to have been subordinate to, and consequent upon, the fracture, as the ligamentum teres has been found entire. This was the case in one instance recorded by Dr. M'Tyer, and another somewhat similar by Mr. Wormald, has been already alluded to. (See DISLOCATIONS.) The symptoms will be somewhat perplexing. They will resemble for the most part those of dislocation, either on the dorsum ilii or into the sciatic notch, according as it is the upper or the posterior part of the acetabulum which is broken off; but there will be crepitus more or less evident when the limb is moved, the reduction will be accomplished without difficulty, but after

reduction the displacement will recur; all of which circumstances happen equally in fracture of the neck of the femur. Two cases related by Dr. M'Tyer were mistaken for fractured neck of the femur, a third case was considered to be a dislocation on account of the difficulty met with in the reduction. (See *Wm. M'Tyer, On Fractures connected with the Hip-Joint; Glasgow Med. Journ.* No. xiii.)

Such cases as these require the greatest circumspection to distinguish them with certainty; if the surgeon can succeed in feeling the head of the bone in its new situation, all doubt will be removed, otherwise the means for arriving at a correct diagnosis are very insufficient.

In the treatment the principal indication is to maintain the reduction of the dislocation while union of the fracture is going on. M. Maisonneuve succeeded in doing so by keeping the limb in a position of extreme abduction, in order to throw the head of the femur against the bottom of the acetabulum, and to prevent it from acting upon the detached fragment of bone. This plan might therefore be tried, but should it prove insufficient, permanent extension of the limb according to the method used in fractures of the thigh should be resorted to.]

FRACTURES OF THE FEMUR.

[Fractures of the femur, like those of the humerus, will require to be subdivided into—1. Fractures of the upper extremity or neck. 2. Fractures of the shaft. 3. Fractures of the lower extremity or condyles.]

1. Fractures of the Neck of the Femur.

As this is a subject which has excited considerable discussion, the reader cannot be too particular in noticing that three distinct kinds of fracture, very different in their nature, treatment, and result, were formerly confounded together under the name of "fractures of the neck of the thigh-bone;" for much of the dispute that has prevailed whether these fractures will unite like those of other bones, seems to have proceeded from the three species of fracture not having been properly discriminated. Two of the cases unite by means of callus, like other fractures; but the other, as it usually occurs, is conceived by some surgeons not to admit of a similar mode of union; or, at all events, they declare that such a termination is very difficult to procure. Sir A. Cooper has, therefore, divided these cases, first, into fractures which happen through the neck of the bone, entirely within the capsular ligament; being the examples in which a union by bone had not, some years ago, presented itself to his notice: secondly, into fractures through the neck of the bone at its junction with the trochanter major, which fractures are of course external to the capsular ligament; thirdly, into fractures through the trochanter major, beyond its junction with the neck of the bone. (*On Dislocations, &c.* p. 114—116.) [Sir A. Cooper has also described a fracture of the trochanter major, by which this process is broken off from the rest of the bone, without any further fracture of the neck or shaft.]

Fractures of the neck of the thigh-bone are infinitely more frequent than dislocations at the hip, and may arise from a fall, either upon the great trochanter, the sole of the foot, or the knee.

According to Desault and Dupuytren, the first accident produces the injury much more frequently than the two latter. (*Clin. Chir.* t. ii. p. 90, 93.) The causes are arranged by Dupuytren, according to their greater frequency, as follows: 1. Falls on the great trochanter. 2. Direct violence, as that from gunshot. 3. Falls on the foot or knee. 4. Muscular action, as reported of a negro afflicted with tetanus. Of thirty cases which were seen by Desault, four-and-twenty arose from falls on the side of the pelvis. Sir Astley Cooper observes, that in London the fracture within the capsule is most commonly produced by a person slipping off the edge of the foot-pavement. He admits, however, that the accident is frequently caused by a fall upon the trochanter major. (*Surgical Essays*, part ii. p. 35, 36. Also, *Larrey, Journ. Complém.* t. viii. p. 98. 8vo. Paris, 1820.) [It is not improbable that in some of the cases attributed by the French surgeons to falls upon the trochanter, the fall may have been subsequent to the fracture, which was really produced by violence applied to the sole of the foot, or knee.] Dupuytren, and all surgeons of experience, recognise the truth of the remark made by Sir Astley Cooper, namely, that a fracture of the neck of the thigh-bone, within the capsular ligament, seldom happens but at an advanced period of life; and the reason of the facility with which the injury takes place in old persons, he ascribes to the interstitial absorption which that part of the femur undergoes in individuals past a certain age, whereby it becomes shortened and altered in its angle with the shaft of the bone. Dupuytren never had a case of fracture of the neck of the femur in a child, and he notices the great rarity of such an accident in young persons. (See *Clin. Chir.* t. ii. p. 82.) He refers, however, to one example in a boy, aged 15, as recorded by Sabatier. (*Mém. de l'Acad. Royale de Méd.*) Another, I think, has been published by Mr. Stanley. (See *Méd. Chir. Trans.*) Possibly some cases, supposed to have been fractures, might have been separations of the epiphyses. (See *Dupuytren, Clin. Chir.* t. ii. p. 90.) Fractures of the neck of the thigh-bone, within the capsule, are more common in women than men. (*J. Wilson, On the Skeleton, &c.* p. 245. *A. Cooper, On Dislocations, &c.* p. 122.)

Almost all the patients under Dupuytren, in the Hôtel Dieu, with fractures of the neck of the femur, were more than fifty years of age; and he found the frequency of the accident increase with old age. The reason of the rarity and frequency of the accident at different periods of life, is correctly ascribed by him to the anatomical disposition of the parts, which is not the same in different ages and in both sexes. In childhood the axis of the neck of the thigh-bone approaches that of the shaft; and the great trochanter forms but a slight prominence. Falls on this process were observed by Dupuytren to be the most common cause of the accident; and the frequency of the injury he found to be in a direct ratio to the degree of prominence of the great trochanter, or dependent upon the length of the neck of the bone, and the angle formed by it with the shaft. In children the trochanter projects but little, being concealed under the prominence of the os innominatum. Hence, in falls upon the side of the pelvis, the violence does not operate upon it. Dupuytren notices, in addition to the above facts, the greater flexibility of the

neck of the femur in a child; the diminutive breadth of the pelvis; and the abundance of adipose cellular tissue protecting the great trochanter.

In adults under a certain age fracture of the neck of the thigh-bone is rare, yet less so than in children. The phosphate of lime, as Dupuytren observes, has accumulated in the skeleton, though not so copiously as in old subjects; the neck of the femur is much longer; the angle formed with the body considerably more marked; consequently a greater projection of the trochanter, and an increased facility for the operation of the causes productive of fracture of the neck, whether they act from below upwards, or from above downwards. But, as Dupuytren further explains, this length of the neck of the bone, and projection of the great trochanter, differ according to the period of life, the sex, and the individual. In women the neck of the femur is longer, the great trochanter more prominent, and consequently the frequency of fractures of the former parts greater than in men. The bulk and fulness of the muscles, which deaden the effect of falls in male adults, of course lessen the frequency of these fractures in them; while, on the other hand, the accident is common in those male adults whose conformation approximates to that of women in the breadth of the pelvis, the length of the neck of the femur, and the projection of the great trochanter. (See *Dupuytren, Clin. Chir.* t. ii. p. 83—86.)

In advanced life the pelvis retains its extreme width, the great trochanter is prominent, the neck of the femur inclined to a right angle, the organised substance of the bones lessened, and the phosphate of lime so redundant as to render the bones very brittle. These circumstances, together with the diminished quantity of adipose cellular tissue, and the flaccidity and atrophy of the muscles, account for the frequency of the accident in old men.

The division is more frequently transverse than oblique; the neck being sometimes, in the former case, wedged in the body of the bone, as Desault found in several instances; a model of one of which, in wax, is preserved at Paris, and the natural specimen of which was in the possession of Bichat. A fracture of the neck of the thigh-bone is sometimes complicated with one of the trochanter major.

With respect to the diagnosis of a fracture of the neck of the femur, an acute pain is felt, a sudden inability to walk occurs, and the patient cannot raise himself from the ground. The latter circumstance, however, is not invariable. In the fourth vol. of the *Mém. de l'Acad. de Chirurgie*, a case is related in which the patient walked home after the accident, and even got up the next day. Desault published a similar example; and several others fell under the observation of Dupuytren. (See *Clin. Chir.* t. ii. p. 96.) The locking of one end of the fracture in the other affords an explanation of this circumstance.

The diagnosis is not always free from considerable difficulty: some individuals have the rational signs of the accident, and yet are not the subjects of it; while others, who have really encountered it, may not exhibit the symptoms of it. Sometimes a fall producing a contusion of the hip will bear some resemblance to a fracture of the neck of the femur, while the same cause occasioning the latter injury, may not hinder the patient from getting up and walking. Dupuytren concurs with other surgeons

in ascribing this fact to the fracture being situated within the capsular ligament, and the fragments not being displaced, but the lower wedged in the upper. Then the circumstances of their becoming separated after a longer or shorter time, and of the fracture then being rendered manifest, he imputes to the fragments changing their situation with respect to one another, either in consequence of the weight of the body, the action of the muscles, or the removal of some portion of the fragments themselves. I think, however, with Mr. R. W. Smith, that it is more frequently owing to the fibrous covering of the neck giving way after a certain time (see *Dubl. Journ. of Med. Science*, vol. vi. p. 213); and his observation seems well founded, that a sudden retraction, at a period more or less remote from the receipt of the injury, denotes a fracture within the capsule. The shortening and rotatory displacement of the limb, arising from the displacement of the fragments, then leave no doubt of the fracture, provided they are connected with no other cause than a fall a few days previously. Sometimes, as Dupuytren adds, the two foregoing signs do not occur till fifty, sixty, or eighty days after the commencement of the treatment by rest and extension, owing to the callus having yielded to the contraction of the muscles or the weight of the trunk. Dupuytren further explains, that the internal fragment may be wedged in the external one, directed either forwards or backwards; that, when it happens, the shortening of the limb is only to the extent that one fragment is impelled into the other; and that this may account, in some cases, for the occasional inversion of the foot, which is an exception to what is usually noticed. (See *Clin. Chir.* t. ii. p. 97—100.)

Another remark made by Dupuytren is perfectly correct, namely, that, when there is displacement, the nature of the accident is easily made out; but that, when no displacement exists, a suspicion may be entertained of the fracture; yet there can be no certainty about it. When the shortening of the limb is only to the extent of a few lines, the discrimination of it from what is produced by the ascent of the pelvis from a contusion, is attended with difficulty; but the diagnosis is plainer if the retraction amounts to half an inch, an inch, or an inch and half, or two or three inches. The latter degrees of shortening rarely occur but consecutively, and when the patient has attempted to walk. (*Dupuytren, Clin. Chir.* t. ii. p. 103.)

The dissections made by Dr. Colles led to the discovery, that sometimes the solution of continuity does not extend completely through the neck of the femur. (See *Dublin Hospital Reports*, vol. ii.) Three cases proving this fact are adduced; a fact which at once explains the ability of some patients to walk directly after the injury, and the absence of all retraction of the limb. According to Mr. Amesbury, incomplete oblique fractures of the neck of the femur are easily produced in the recently dead subject. (*On Fractures of the Upper Third of the Thigh-bone*, p. 3.) [See also on this subject, R. Adams, *on Abnormal Conditions of the Hip-joint, in the Cyclopædia of Anatomy and Physiology*. Mr. R. W. Smith, however, expresses considerable doubt as to the reality of a partial fracture of the neck of the femur, and has shown, by actual examination of the specimens, that in some, at any rate, of the alleged examples, the fracture of the cervix was complete, and the trochanter likewise broken.]

A shortening of the limb almost always takes place; "the leg becomes," according to Sir Astley Cooper, "in a case of fracture within the capsule, from one to two inches and a half shorter than the other; for the connexion of the trochanter major with the head of the bone, by means of the cervix, being destroyed by the fracture, the trochanter is drawn up by the muscles as high as the ligament will permit, and consequently rests upon the edge of the acetabulum, and upon the ilium above it." (*On Dislocations, &c.* p. 117.)

With respect to the degree of retraction specified by Sir Astley Cooper as attendant on fracture of the neck of the femur within the capsular ligament, its correctness is not admitted by some surgeons; Mr. R. W. Smith, of Dublin, declares that it is completely opposed to the result of his experience; nor does he conceive it possible that the capsule of the hip-joint could admit of displacement to the extent of two inches and a half without being extensively torn; an occurrence very rare indeed; and if, as is frequently the case, the fibrous reduplications, which constitute the periosteum of the neck of the bone, remain entire, or nearly so, retraction may be almost completely prevented. In several instances of recent fracture of the neck of the femur within the capsule, Mr. Stanley found this to be the case. (See *Med. Chir. Trans.* vol. xiii.) Mr. R. W. Smith refers also to the statements of Boyer and Earle, in support of the same view; and he adds, "But when the fracture is external to the capsule, there is an opportunity for retraction occurring to its greatest degree: there is, in fact, nothing to prevent the full force of muscular action upon the lower fragment of the bone, while, at the same time, the upper is forced downwards by the weight of the body." (See *Dublin Journ. of Med. Science*, vol. vi. p. 207.)

Mr. Smith excepts from this observation the case in which the upper fragment is driven into the cancellated texture of the lower, the ascent of which is not only prevented, but sometimes the restoration of the limb to its original length. Here the degree of shortening will be much less than what is usually the result of a fracture external to the capsule; and this relative position of the fragments, Mr. Smith conceives, ought to be suspected whenever unusual difficulty is experienced in detecting crepitus, and extending the limb to its original length.

[In the impacted variety of the extracapsular fracture, all the leading symptoms are much less strongly marked than in an ordinary case. Instances have even occurred in which the patient has raised himself from the ground after the fall which caused the fracture, and has walked a considerable distance, bearing his weight upon the injured limb. Such cases have probably not unfrequently been mistaken for mere contusions of the hip, and great care may be required to distinguish them. On close examination, however, some shortening and eversion of the limb may usually be detected.]

In the extracapsular fracture, according to Mr. R. W. Smith, whose opinions are founded upon the examination of a large number of specimens, there is always a second fracture traversing some part of the trochanteric region of the femur, and separating either a portion or the whole of the greater trochanter, or the greater and lesser trochanter together. The extracapsular fracture, he

thinks, is always in the first instance impacted, and the second lesion of the bone is the necessary result of the forcible impaction of the broken cervix into the shaft of the femur. It depends, he thinks, principally upon the violence with which the injury has been inflicted, whether the neck of the bone shall remain impacted or not. If the force has not been very great, the neck of the femur is wedged in between the trochanters, and one or both of these processes are split off from the shaft, while, if the periosteum and surrounding fibrous structures have not been injured, these broken portions of the trochanters are still held firmly in their places, and the impacted cervix does not become loosened; but if the force has been more considerable, the trochanters are not only broken from the shaft of the femur, but are so far displaced and separated from their connexion with the soft parts, that the cavity, into which the superior fragment has been received, is destroyed, and the impacted cervix, thus set free, no longer opposes the ascent of the inferior fragment, and the case then presents the character of the ordinary extra-capsular fracture, with great shortening of the limb. (*R. W. Smith, On Fractures, &c.* p. 17. Dublin, 1847.)

Impaction may occur in the intracapsular as well as in the extracapsular fracture, though it is not so frequent as in the latter case, and it is, as Mr. R. W. Smith describes it, a dovetailing together of the fragments, rather than a true impaction, which usually takes place. In all the examples which he has examined, the head of the bone appeared sunk below its natural level, and the upper margin of the head was buried in the cancellated tissue of the neck, while the lower margin of the neck penetrated the reticular structure of the head of the bone. These are precisely the cases in which the very rare event of union by bone is most likely to occur.]

In general, the degree of shortening when the fracture is within the capsule, I believe, with Mr. Smith and others, often depends upon the extent to which the fibrous reduplications have been torn. According to this gentleman's investigations, the degree of shortening, when the fracture is within the capsular ligament, varies from a quarter of an inch to one inch; when external to the capsule, from one inch and a half to two inches and a half. At the same time, the great differences in the direction of the solution of continuity must have, as Dupuytren has admirably explained, vast influence upon the degree of retraction, as well as upon the rotatory displacement of the limb. (*See Clin. Chir.* t. ii. p. 113.)

The action of the muscles drawing upward the lower end of the fracture, and the weight of the trunk in propelling downward the pelvis and upper end of the fracture, are the two causes of the shortening of the limb. In general a slight effort suffices for the restoration of the natural length of the limb; but the shortness recurs almost as soon as the extension ceases. "This evidence of the nature of the accident continues," as Sir A. Cooper correctly remarks, "until the muscles acquire a fixed contraction which enables them to resist any extension which is not of the most powerful kind." (*Surgical Essays*, part ii. p. 31.) Goursault, Sabatier, and Dupuytren found that sometimes the shortening of the member did not take place till a long while after the accident. Dupuytren refers to examples in which several hours, and even from

two to thirty days, elapsed, before any displacement of the fragments took place, and which was then produced either by the patient's own movements, or by the surgeon's examination of the part. (*Clin. Chir.* t. ii. p. 96.) In opposition to the common belief that the limb is shortened, Baron Larrey asserts that the member is at first actually lengthened. (*Journ. Complém.* t. viii. p. 99.) This statement I have never seen confirmed, and it is contradicted by daily experience. And, to prove how widely Larrey differs from Sir A. Cooper, the following passage will suffice. "In order to form a still more decided judgment of this accident (says the latter writer), after the patient has been examined in a recumbent posture, let him be directed to stand by his bedside, supported by an assistant, so as to bear his weight upon the sound limb. Immediately he does this the surgeon observes most distinctly the shortened state of the injured leg, the toes resting on the ground, but the heel not reaching it, the everted foot and knee, and the diminished prominence of the hip." (*Surgical Essays*, part ii. p. 34.) The lessened projection of the trochanter major arises from its not being supported by the neck of the bone, as it always is in the natural state of the parts. A swelling is observable at the upper and front part of the thigh, always proportioned to the retraction, of which it appears to be an effect.

The projection of the great trochanter is almost effaced. Directed upwards and backwards, this eminence becomes approximated to the crest of the ilium; but, if pushed in the opposite direction, it readily yields; and when it has arrived at its natural level, the patient becomes capable of moving his thigh.

The knee is a little bent. Abduction of the limb always occasions acute pain, and it is noticed by Sir A. Cooper, that the rotation inwards is particularly painful, because the broken extremity of the bone then rubs against the capsular ligament. (*Vol. cit.* p. 33.) If, while the hand is placed on the great trochanter, the limb is rotated on its axis, this bony projection may be felt revolving on itself, as on a pivot, instead of describing, as in the natural state, the segment of a circle, of which the neck of the femur is the radius. This symptom, which was first particularly noticed by Desault, is very manifest when the fracture is situated at the base of the neck; less so when at its middle; and it is not very perceptible when the breach is near the head of the bone. In the rotatory motions, the lower fragment rubbing against the upper one, produces a distinct crepitus, which, however, is not an invariable symptom. In fact, as Sir A. Cooper has explained, it is not discoverable while the patient is lying upon his back with the limb shortened; but if the leg be drawn down so as to bring the limbs to the same length, and rotation be then performed, especially inwards, the crepitus is sometimes observed, in consequence of the broken ends of the bone being thus brought into contact. (*On Dislocations, &c.* p. 121.)

It appears to Mr. Amesbury that the head of the bone moves so readily in the acetabulum, "that the least impetus, even through the periosteum and reflected membrane (supposing them to be entire) will cause it to move simultaneously with the shaft; and, if it should do so in the same relative proportion, crepitus cannot be felt. If crepitus be not elicited by bending the limb upon the pelvis,

the surgeon may try to produce it by causing the limb to be *gently rotated* while he endeavours to fix the head of the bone by pressing it with his fingers back against the acetabulum." (*On Fractures of the Upper Third of the Thigh-bone*, p. 15.) [It should be remembered, however, that mischief may arise from too great anxiety to obtain the evidence of crepitus, for the fibrous reduplications which are reflected upon the neck of the bone from the insertion of the capsular ligament, and which sometimes remain entire, and are of great service in preventing displacement, may be ruptured by the attempts to communicate rotatory movements to the limb.]

The toes are usually turned outward; a position which Sabatier considers as the inevitable effect of the fracture, though Paré and Petit noticed that it did not constantly occur. Two cases adduced by these illustrious surgeons were not credited by M. Louis; but the experience of Desault fully confirmed the possibility of inversion of the limb. As Sir A. Cooper has remarked, three or four hours generally elapse before the turning of the limb outward is rendered most obvious by the fixed contraction of the muscles. (*Surgical Essays*, part ii. p. 32.) The inversion of the limb, however, in fractures of the neck of the femur, is rare; Dupuytren, in his immense practice, never having seen it but once or twice. (*Clin. Chir.* t. ii. p. 105.) Mr. R. W. Smith has met with three cases, in one of which the injury was within the capsule. (*Dub. Journ. of Med. Science*, vol. vi. p. 215.)

Mr. Langstaff dissected a case in which the great toe was in the first instance everted, but subsequently turned inwards when the patient began to use the limb. The preparation shows the fracture to have been within the capsular ligament, close to the head of the bone, and gives a decided refutation to the opinion of the length of the broken portion attached to the trochanter being the cause of the inversion, inasmuch as this part has been removed by absorption. The point of the foot was everted, whilst it retained its proper length, and only became inverted by a wise provision of nature to assist progression after it had begun to be shortened. This circumstance was illustrated in the person of Henry West, a boy from whom Mr. White, of the Westminster Hospital, removed the head, neck, and part of the trochanter of the left thigh-bone, in consequence of scrofulous disease of the hip-joint, attended by abscess. He recovered after the removal of the bone. The thigh was three inches and a half shorter than the other, and the toes turned inwards, not only in walking, but when he lay on his back in a quiescent posture, or prepared for sleep. (*Guthrie, Med. Chir. Trans.* vol. xiii. p. 109.) The possibility of the foot being turned inwards directly after the accident, is the subject that now more immediately interests us. Of this occurrence an example is reported by Mr. Stanley. "A middle-aged man fell in the street, and his hip struck the curb-stone. The immediate consequences were, that the limb was inverted and shortened to the extent of an inch, and no crepitus could be discovered. It was presumed that a dislocation had occurred, and accordingly an extension of the limb was made; and so great was the constitutional irritation occasioned by the repeated trials to reduce the supposed dislocation, that the man died about five months from

the time of the accident. In the dissection of the hip a fracture was found, extending obliquely through the middle of the neck of the femur, but *entirely within the capsule*. A portion of fibrous and synovial membrane on the anterior side of the neck of the bone had escaped laceration."—"In a male subject that had been brought for dissection, it was observed that the left lower extremity was turned inwards and considerably shortened. On examining the hip a fracture was found extending through the neck and shaft of the femur. The neck had been broken at its junction with the shaft, and a fracture had extended from the upper part of the trochanter major downwards at the posterior side of the femur, a little below the trochanter minor. The upper part of the shaft was thus split into two portions, one of which was of sufficient magnitude to include the trochanter minor and nearly the whole of the trochanter major.

"In the two last cases, it may be asked, to what cause the inversion of the limb should be attributed? Whether to the direction of the fracture? If not, whether there be any other circumstance adequate to its explanation? In the instance of fracture within the capsule, the portion of the synovial and fibrous membrane which had escaped laceration on the anterior side of the neck of the bone might probably prevent the limb from being turned outwards; but (says Mr. Stanley) why it should have been turned inwards, I confess myself unable to explain. In the instance of fracture without the capsule, by considering the direction of the fracture, in reference to the attachments of the muscles, we obtain an explanation of both points. For, as nearly the whole of the muscles that rotate the thigh outwards were connected with the separated portion of bone, they must have ceased to influence the limb in one direction, and of course have left their antagonists at liberty to turn it in the other; and the fractured surfaces being permitted to unite, without any change in the position of the limb, the inversion would become permanent." (*Med. Chir. Trans.* vol. xiii. p. 508.) Respecting one part of this statement, I think with Mr. Smith (*Dub. Journ. &c.* vol. vi. p. 215), that the circumstance of the fibrous membrane remaining entire upon the front of the neck of the bone, would scarcely account for the limb not being everted. Another explanation of the cause of the inversion of the foot in certain fractures on the outside of the capsular ligament has been given by Mr. Guthrie. "When (says he) the fracture has taken place in such a manner as to be external to the insertion of these rotators outwards, yet sufficiently within the insertion of the glutæus medius and minimus, so as not to deprive them of their due action, the toe will be turned inwards, and must always be so; or remain without any alteration of position, according to certain variations in the inclination of the fracture, affecting the power of these muscles." In the instance recorded by Mr. Guthrie, the little trochanter was broken off; but whether it be an essential complication, he conceives, must be determined by future observation. (Vol. cit. p. 112.) The principles on which this gentleman founds his explanation have since been corroborated by the particulars of a case that was examined by Mr. Syme. (See *Edin. Med. Journ.* April 1826.) The reason of the foot being occasionally inverted, even when the fracture is quite within the capsular ligament, still remains,

however, a point in surgery requiring explanation. The eversion or inversion of the limb, Dupuytren ascribes to the obliquity of the fragments. If the internal fragment is carried backward, and the external one forward, then, says he, eversion will take place; but on the contrary, if the fracture be oblique in the inverse direction, there will be inversion of the limb. (*Clin. Chir.* t. ii. p. 109.)

[Mr. R. W. Smith is of opinion that the occasional occurrence of inversion should be ascribed rather to the relative position of the fragments than to the action of those muscles which rotate inwards; for the rotators outwards, whose influence the fracture does not affect, still preponderate over their antagonists. In every case of fracture, accompanied by inversion of the foot, which he has had an opportunity of examining after death, *the inferior has been placed in front of the superior fragment*. Cruveilhier also has recorded a case of fracture with inversion, in which, after death, this relative position of the fragments was found. This is in contradiction to the opinion of Dupuytren above quoted; but, as Mr. Smith explains, it is probable that this surgeon's views have been misstated by the editors of the *Leçons Orales*, and that his real opinion was, as stated by Sanson, that inversion of the foot occurred when the lower fragment was placed in front of the superior. Inversion of the foot has been noticed both in the intra-capsular and in the extra-capsular fracture, but it appears to be most frequent in the latter variety. Mr. R. W. Smith states that he has met with seven examples of inversion, and in five of these the fracture was external to the capsular ligament.]

Mr. Porter had an opportunity of dissecting the hip-joint, in a case where the patient, an old female, died the day after the accident. When first brought to the hospital, she could bend the knee and draw up the foot by the action of the muscles of the limb alone. Afterwards she lost this power. The limb was not shorter than the other; neither was the toe everted. At the post-mortem examination the limb was from a quarter to half an inch shorter than the other, and "the foot was in a state of semi-eversion." The capsule was found perfect, and, on dividing it posteriorly, a transverse fracture of the neck of the femur was detected close to the head of the bone, and, of course, entirely within the capsule. The fragments were but little displaced, *being held together by the synovial membrane and periosteum*. These latter were partially detached, and a portion of the lower surface of the neck of the bone denuded; but the fibres, removed from the bone, were gathered together into a bundle, forming a kind of ligament of a triangular shape; the base being at the edge of the head, the apex at the point of reflexion of the synovial membrane on the capsule. *This appeared to be very tense and strong, and made considerable resistance to a separation of the fragments*. "This case is interesting, as proving that in fractures completely within the capsule the limb is not at all, or but slightly, shortened; and that the chief obstacle to such shortening is the periosteum of the neck, and the reflected synovial membrane." (*W. H. Porter, in Dub. Journ. of Med. Science*, vol. x. p. 243.)

The dislocation upon the dorsum of the ilium, that into the sciatic notch, and fracture of the neck of the femur, *attended with inversion of the foot*, are to be distinguished from each other, according to Mr. Guthrie, by comparison, or a due estimate of

the degree of inversion. In the first case the inversion is complete, the great toe resting against the instep of the opposite foot; in the second, it is less complete, the great toe resting against the ball of the corresponding toe of the opposite foot; and in the third, it is still less complete. And, as Mr. R. W. Smith justly observes, the nature of the injury is rendered still more evident by observing the facility with which, in the case of fracture, the foot may be everted, the thigh flexed upon the abdomen, and the limb restored to its natural length by extension; and comparing its free, loose, powerless condition with its almost immovably fixed state in dislocation. (*See Dub. Journ. of Med. Science*, vol. vi. p. 218.) [The accident most liable to be confounded with dislocation upon the dorsum ilii, is fracture of the neck of the femur, with inversion of the foot, especially if it is combined with fracture of the trochanters, which is almost invariably the case in the extracapsular variety. A direct source of mistake may then arise from the positive resemblance of the fractured portion of the trochanter to the head of the femur, the former occupying the same place as the latter would do in dislocation. (*R. W. Smith, On Dislocations, &c.* p. 23.)]

The ordinary position of the toes outward is commonly, and I believe correctly, imputed to the action of the rotator muscles, and the adductors. Bichat conceived, however, that if this doctrine were true, such position ought always to exist; and he reminds us that all the muscles which proceed from the pelvis to the trochanter and upper part of the outer fragment, are, with the exception of the quadratus, in a state of relaxation, by the approximation of the femur to their point of insertion; and that the contracted muscles would not allow the foot to be so easily turned inward again. Hence Bichat thought it probable that the weight of the foot itself might pull the limb into the position in which it is commonly found. On the other hand, it is remarked by Sir A. Cooper that any one may satisfy himself that the rotation of the limb outwards is in part owing to the muscles, by feeling the resistance which is made to rotation inwards, which resistance, however, he thinks may in some measure depend upon the length of the portion of the neck of the femur, which remains attached to the trochanter major, and rests against the ilium. (*Surgical Essays*, part ii. p. 32.)

In addition to the foregoing observations respecting the diagnosis, it is to be remembered, that a fracture within the capsular ligament seldom happens but at an advanced period of life, and is much more frequent in women than men. (*Sir A. Cooper, On Dislocations, &c.* p. 123.)

The observations of Boyer, R. W. Smith, Porter, and others, prove that a fracture of the neck of the thigh-bone, on the outside of the capsular ligament, is attended with a greater shortening of the limb than a fracture within it. A fracture on the outside of the capsule is frequently met with in persons under fifty, though it may and often does occur in older subjects. Also, while the fracture within the capsule takes place from very slight causes, this is generally the result of great violence, severe blows, falls, and the passage of heavy carriages over the pelvis. The crepitus can be easily felt, without previously drawing down the limb, and the case is characterised by greater suffering than what is usually noticed when the fracture is within the capsule. But the most im-

portant circumstance in which a fracture on the outside of the capsule differs from one within it, is in its readily admitting of bony union, which it is much more difficult to accomplish in the latter case. (See *Sir A. Cooper, On Dislocations, &c.* p. 185, &c.)

Many years ago it was supposed that fractures of the neck of the thigh-bone could not be cured without some shortening of the limb, and lameness. Ludwig, Sabatier, and Louis, broached this doctrine, and imputed the circumstance to the destruction of the neck of the bone. That this commonly happens, has been well ascertained. In several specimens which Mr. Crosse examined in different museums at Paris, whether imperfect union, or no union at all, had followed the fracture, this absorption of the neck of the bone had taken place to a great extent, and in some to so great an extent, that the articulating surface of the bone which plays in the acetabulum, rested between the trochanters consolidated to the body of the bone by ligamentous union, and the thickening of the surrounding parts, whilst all the intervening neck of the bone was absorbed. (See *Sketches of the Medical Schools of Paris*, by J. G. Crosse, p. 90.) M. Roux has also nearly always found the neck of the femur shortened and deformed after its reunion. (*Parallèle de la Chir. Angloise avec la Chir. Française*, p. 178.) The specimens in the museum of University College exhibit the usual disappearance of more or less of the same part. Desault, however, in his practice, is said to have rarely met with instances of lameness from such a cause.

A question formerly much agitated (see *Earle's Practical Obs. in Surgery*, Lond. 1823; and *Amesbury's Obs. on the Nature and Treatment of Fractures of the Upper Third of the Thigh-bone, &c.* Lond. 1829, ed. 2) was, whether reunion by bone ever follows cases in which the fracture is entirely within the capsule, and the head of the bone insulated, except at its attachment to the acetabulum by the round ligament? Many years ago the decision of the French surgeons was in the affirmative, and they believed the fact to be actually demonstrated by preparations in their museums. M. Roux sent a specimen to Sir A. Cooper, with the hope of producing conviction; but this eminent surgeon was not satisfied with the evidence, because the traces of reunion in that preparation appeared to him to indicate a sort of fracture, where the internal fragment still retained some connexion with the capsular ligament. (*Roux, Parallèle de la Chirurgie Angloise, &c.* p. 179, 180.) In fact, it was a case in which the fracture happened at the junction of the cervix with the trochanter. Sir A. Cooper never denied the possibility of what M. Roux and others alleged, but only stated, that in all the examinations which he had then made of *transverse fractures of the cervix femoris, within the capsular ligament, he had never met with a bony union, or with any which did not admit of motion of one bone upon the other.* (*Surgical Essays*, part ii. p. 39.) Since that period, however, Sir Astley Cooper has satisfied himself that osseous union sometimes takes place, and he has in his own collection a most unequivocal specimen of it, which he was kind enough to show to me about two years ago. The possibility of bony union is now universally acknowledged; but the cure in this way is far less

frequent than that by means of a ligamentous connexion. Sir Astley Cooper ascribes the common want of bony union to the fragments not being in contact, and duly pressed against each other, and to the little action in the head of the bone separated from the cervix, "its life being supported solely by the ligamentum teres, which has some few vessels ramifying from it to the head of the bone." These vessels, though neither large nor numerous, may yet, according to Amesbury and Dupuytren, be adequate to the nutrition of the upper fragment. Besides, it is observed by Dupuytren that the synovial membrane, which invests the cartilage, forms a little cul-de-sac at its base, and is distinctly covered by portions of reddish cellular tissue, in which there are many vessels. (See *Clin. Chir.* t. ii. p. 118.) Mr. Mayo gives two cases exemplifying the appearances usually found on dissection; and observes, "there are features in them which make it sufficiently clear that the absence of bony union does not result from imperfect nutrition, or inadequate supply of blood to the separated portion." (*Outlines of Human Pathology*, p. 9.) This gentleman concurs with Dupuytren, Cruveilhier, and others, that in the union of the shafts of long bones, the surrounding tissues take a prominent part in the act of reparation. But in the fracture of the neck of the thigh-bone within the capsule, these tissues are excluded by the untorn synovial and capsular membranes from communicating with the fracture. "They are sometimes, indeed, seen to make the ordinary effort towards reparation of the adjacent fracture. Thus, a portion of an ossified provisional callus is often met with external to the attachment of the capsular membrane to the neck of the femur. But the effort is ineffectual; the callus cannot reach the fracture, whether it remains entirely disunited or is glued together by an exudation from the ends of the broken bone. In the cases in which union takes place (continues Mr. Mayo), I believe the process of ossification to be extremely slow. Such instances occur in those only who are not greatly advanced in life at the time of the fracture; and in whom, through the care with which the joint is kept at rest, direct union by soft substance takes place between the separated portions." (*Mayo, ib.*) [The impossibility of keeping the part at rest has probably much more to do with causing the non-union than the exclusion of the surrounding tissues. If the ends of the fracture could be maintained in continued and immoveable contact, they would, except in the very old and feeble, possess in themselves sufficient vitality for their re-union; and probably the only cases in which union has been effected, are those in which this contact has been secured, either by impaction or by the non-laceration of the fibrous covering of the neck.] For the particular appearances found in the dissection of many of these cases, I must refer to the statements of Dr. Colles (*Dublin Hospital Reports*, vol. ii.), and to Sir Astley Cooper's own account, from which it seems that in most instances "where no ossific union is produced, nature makes slight attempts for its production upon the neck of the bone, and upon the trochanter major, but scarcely any upon the head of the bone; and that, if any union is produced, it is by ligament only." (Vol. cit. p. 46. Also, *Mayo's Outlines of Human Pathology*, p. 9.) Mr. Wilson's

observations are all in support of the same explanation (*On the Skeleton*, p. 247); and he adverts to two preparations in the museum of the College of Surgeons, which were supposed to be proofs of a bony reunion of the neck of the femur, subsequently to a fracture within the capsular ligament; but (says Mr. Wilson) "I have very attentively examined these two preparations, and cannot perceive one decisive proof in either of the bone having been actually fractured." One of these cases was published by Mr. Liston, in the *Edin. Med. and Surgical Journ.* Lastly, Dr. Colles of Dublin dissected several cases in which the neck of the femur had been broken: in one, where the injury was within the capsular ligament, "no effort of nature had been made to create a reunion between the two pieces of the fracture, and the stability of the limb had depended upon the strength of those ligamentous bands by which each piece was connected with the capsular ligament of the joint, aided, no doubt, by the extraordinary thickness which the capsular ligament had acquired." (*Dublin Hospital Reports*, vol. ii. p. 336.) In the two first instances reported by this author, "The broken surfaces moved on each other, and were converted into a state approaching to ivory. No attempt had been made to reunite the fracture, and the pieces of bone were held in apposition only by new ligamentous productions from the capsular ligament, which were inserted into the external surfaces of each piece. In No. 3 there had been a slight attempt made at reunion. In Nos. 7, 8, and 9 we observed a phenomenon, which, I believe, is now for the first time mentioned, a fracture of only part of the bone. No. 6 presented us with that mode of reunion, which some have supposed the most perfect of which this fracture is susceptible; while Nos. 10 and 11 exhibit a mode of reunion very little inferior to callus in point of firmness, but very different in its nature, and which, I conceive, is peculiar to the fracture of the neck of the femur." Dr. Colles also found that in all these cases (except, perhaps, No. 5) the capsular ligament was not lacerated. In every instance, however, there was an increased thickness of the capsule, and a removal of all, or the greater part, of the neck of the bone. "Although the ligamentous bands seem, in a majority of instances, to have proceeded from the capsular ligament, yet it is evident from No. 6 that these may arise merely from the broken surfaces of the bone; for in this case not a single fibre was attached to the capsular ligament, the new bond of union being covered by the reflected portion of the synovial membrane or periosteum of the neck. We have an illustration of this in Ruysch, tab. 1. Thes. 9." In Nos. 10 and 11 the fragments were united by a cartilaginous substance. In Nos. 7, 8, and 9 the unbroken portion of the neck was so softened, that it more resembled cartilage than bone, and in this state "it was laid down upon the fractured surface, and united to it." (*Dr. Colles, in Dublin Hospital Reports*, vol. ii. p. 353—355.) In the museums at Paris are some preparations which the professors used to exhibit at their lectures, in order to prove that bony union may succeed a fracture within the capsule. These specimens were carefully examined by Mr. Crosse, but none of them proved to him that bony union ever follows where the head of the bone becomes insulated, excepting at its attachment to the pelvis

by the ligamentum teres. (*Sketches of the Medical Schools at Paris*, p. 93.) On the other hand, Boyer observes, that experience fully proves the possibility of uniting such fractures of the neck of the thigh-bone as are situated within the capsular ligament; but he acknowledges that there are certain circumstances which may prevent this desirable event. "From all that has been hitherto said on the prognosis of a fracture of the neck of the femur, we may conclude (says Boyer) that this fracture is more serious than that of any other part of the same bone, because the difficulty of keeping it reduced is greater: that it may in general be reunited, especially in young healthy subjects (in whom, however, be it observed, the accident hardly ever occurs); but more easily when it is situated near the base of the neck than near the head of the bone: that the languid vitality of one of the fragments, and the impossibility of ascertaining whether the coaptation be exact, make the cure slow, and the time necessary for their consolidation uncertain: that the neglect of means adapted to maintaining the limb in its proper length and natural straightness, and the fragments sufficiently motionless, may cause them to unite by an intermediate substance. Lastly, that the situation of the fracture near the head of the femur; the complete laceration of the elongation of the capsule investing the neck of the bone; the great age of the patient; and, particularly, the constitution labouring under some diathesis which affects the osseous system; may render the cure absolutely impossible; that in this circumstance one of the fragments is more or less destroyed by the friction of the other against it, and in the joint a disease is formed, which tends to carry off the patient." (*Mal. Chir.* t. iii. p. 284.) Boyer lays much stress on the complete laceration of the continuation of the capsule over the neck of the bone, as an occurrence preventive of union. But he thinks it does not frequently happen, because the capsular ligament hinders much displacement of the fragment. (*Op. cit.* p. 278.) As for Baron Larrey, he entertains no doubt of the possibility of uniting fractures of the neck of the femur within the capsular ligament, and concludes his tract on this subject with the case of General Fririon, who was perfectly cured after an injury of this description. (*See Journ. Complém.* t. viii. p. 148.)

After the very numerous and careful dissections performed by Sir A. Cooper and Dr. Colles, with the view of ascertaining the state of the joint after fractures of the neck of the thigh-bone, little doubt can be entertained that where the fracture is transverse, and within the capsular ligament, a bony reunion, though not impossible, is at least so rare an occurrence as not to be calculated upon. Those who look upon it as a thing more frequent and easy of accomplishment, have probably not duly discriminated from the foregoing kind of case either fractures extending more or less in the direction of the axis of the neck of the bone, or other fractures external to the capsular ligament. How much, however, the safety of a practitioner's reputation will depend upon the prognosis which is given, must be quite evident; for in the transverse fracture within the capsule, lameness is almost sure to follow, though its degree cannot at first be exactly estimated. (*Sir A. Cooper, Surgical Essays*, part ii. p. 51.)

So far as I am able to judge, Sir Astley Cooper has been the means of introducing a great deal of discrimination into this subject, and, without his able exertions, the important differences in the nature, symptoms, and curableness of the various kinds of fractures of the neck and upper part of the thigh-bone, depending upon their exact situation and direction, might yet have continued very imperfectly comprehended. This remark is made without any intention of deducting from the merits of Desault, Platner, and Mr. John Bell, all of whom long ago expressed their opinion, which, as we know, extends rather beyond the bounds of accuracy, that a fracture within the capsular ligament would not admit of union by callus. (*C. Bell, On Injuries of the Spine and Thigh-Bone*, 4to. Lond. 1824, p. 52, &c.)

Mr. Amesbury believes that all fractures of the neck of the thigh-bone admit of union, whether they be situated quite within the capsular ligament or not, and whether the reflected portion of that ligament be ruptured or not; and he ascribes the usual want of success, not to the nature of the injury, nor to the insufficient circulation in the pelvic portion of the bone, but to the imperfection of the mechanical means employed in the treatment. As, however, the important point under consideration, namely, whether transverse fractures of the neck of the femur, situated entirely within the capsular ligament, admit of bony union, is one that can only be determined by experience, Mr. Amesbury follows up his arguments by a reference to several cases.

The first case adduced was under the care of Mr. Cribbe of Holborn, and is described by Mr. Langstaff, who has the preparation: "The woman was about fifty years of age when the accident occurred. The foot was everted, and there was shortening of the limb at this time; and, after death, it was shorter than the other full two inches and a half. She was confined to bed nearly twelve months: during the remainder of her life, which was ten years, she walked with crutches. This (says Mr. Langstaff, alluding to the preparation) is a specimen of fracture of the neck of the thigh-bone within the capsular ligament: the principal part of the neck is absorbed; the head and remaining portion of the neck were united principally by bone, and partly by a cartilaginous substance. The capsular ligament was immensely thickened, and embraced the joint very closely. The cartilaginous covering of the head of the bone and acetabulum had suffered partial absorption; the internal surface of the capsular ligament was coated with lymph. On making a section of the bone, it was evident that there had been a fracture of the neck within the capsular ligament, and that union had taken place by osseous and cartilaginous media." (See *Med. Chir. Trans.* vol. xiii.) Mr. Amesbury then adverts to Dr. Brulatour's case, reported in the same volume of the latter work. The patient, Dr. James, died about nine months after the injury. The following appearances presented themselves. 1. The capsule a little thickened. 2. The cotyloid cavity sound. 3. The interarticular ligament in a natural state. 4. The neck of the femur shortened: from the bottom of the head to the top of the great trochanter was only four lines, and from the same point to the top of the small trochanter six lines. 5. An unequal line surrounded the neck, denoting the direction of the fracture.

6. At the bottom of the head of the femur, and at the external and posterior part, a considerable bony deposit had taken place. A section of the bone was made in a line drawn from the centre of the head of the femur to the bottom of the great trochanter, so as perfectly to expose the callus. The line of bone, indicated by the callus, was smooth and polished as ivory. The line of callus denoted also that the bottom of the head of the femur had been broken at its superior and posterior parts.

In another example, communicated to Mr. Amesbury by Mr. Chorley of Leeds, a gentleman died twelve months after the accident, and, on examining the hip, the synovial covering was found united with the shortened neck of the bone nearly at the head. Here nature had also thrown out broad ligamentous bands, one on each side of the joint. They were firmly united to the head of the bone. When the soft parts had been removed, the head of the bone was seen depressed in a line with the shaft. The fracture was slightly oblique, commencing at the upper part close against the cartilaginous covering of the head of the bone, and extending downward and outward, so as to terminate in a point at the lower surface of the neck, one inch from the cartilaginous covering of the head. The posterior surface of the shell of the neck had the appearance of having been splintered, so as to make a part of the fractured end of the pelvic portion extend in one situation a little on the outside of the capsular ligament, and where no union had taken place.

In a fourth instance, where the necks of both thigh-bones had been broken at different periods, the parts were examined after the patient's decease. On the right side, the fracture extended through the neck of the bone, in a direction downward and outward. In one part a portion of the reflected membrane remained entire; but was separated from the neck of the bone in such a manner as not to prevent the retraction of the limb. The head of the bone was somewhat excavated; and that portion of the neck attached to the trochanter was partially absorbed. There was no soft substance between the surfaces of the fracture. A bond of union, however, consisting of fibrinous matter, adhered to the sides of the ends of the fracture, and in one part it was strong. No surgical attempt had been made to unite the fracture on the right side. On the left, the neck of the bone had been broken within the capsule, and was firmly united. The cervix was nearly absorbed; and the head was depressed, so as to come within about two lines of the trochanter minor, to which it was united at its base by a small short process of bone. Strong bands of ligament were seen connecting the pelvic portion of bone to the capsule, which had become thickened, and much smaller than natural. There had been a longitudinal fracture of the trochanter major, but quite independent of the injury of the cervix. The fracture of the latter part was united with the head, about two inches and a half below its natural situation; which leads Mr. Amesbury to believe, that what he terms the close coverings of the neck of the bone had been nearly or quite divided. A longitudinal section of the head and neck of the bone showed that the fracture had taken place close to the head. The uniting callus had become cancellated; but he says that the direction of the fracture could be

seen "by the situation of the trochanteral portion of the neck, when examined in different parts of its circumference." (See *Amesbury, On Fractures, &c.* p. 43, &c.)

These, and other cases and dissections, sufficiently establish the possibility of bony union in fractures entirely within the capsular ligament. But this is not the ordinary mode of union; and no doubt is now entertained about many preparations, exhibited as specimens of it, not being good and authentic ones. The rapidity with which absorption proceeds in the head and neck of the thigh-bone after fractures, brings about such changes as must soon greatly obscure the exact original situation and direction of the injury, and particularly the question, whether the injury reached also to the outside of the capsular ligament. That fractures extending beyond the capsular ligament may be united by bone, is admitted by all parties, as well as the fact that those entirely within the capsule are often united with the intervention of fibrous or ligamentous bands. In confirmation of this circumstance, I have already cited the dissections performed by Dr. Colles of Dublin; and, in further proof of it, I refer to the preparations in the museum of the College of Surgeons at Edinburgh, as specified by Mr. B. Bell of that city. (*On Diseases of the Bones*, p. 205, &c. 1828.)

[For an interesting account of several cases of real or supposed osseous union of intra-capsular fractures occurring in the practice of American surgeons, with an impartial discussion of the merits of each example, see *Treatise on Fractures and Dislocations*, by Dr. F. H. Hamilton of Buffalo. Philadelphia. 1860.

The union of fractures external to the capsule is usually attended with very abundant and irregular osseous deposits. These deposits encircle the neck of the femur to a variable extent, but are usually found in greatest quantity along the posterior inter-trochanteric line, though sometimes they are also deposited freely along the anterior line. Mr. R. W. Smith believes the object of their formation is the union of the fracture traversing the inter-trochanteric space, and he states that they are usually proportionate to the amount of injury which the trochanters have suffered. When the trochanter major is merely split or fissured, its fibrous coverings remaining entire, the quantity of new bone is exceedingly small; while it is abundant when a large proportion of the trochanters is broken off and displaced, in consequence of the laceration of the fibrous tissues which invest this region; and it is especially exuberant when the trochanters are comminuted and the fragments displaced, both from the shaft and from each other. The consolidation between the opposed surfaces of the impacted cervix and of the shaft, does not take place so readily or at so early a period as that of the fracture through the trochanter. Mr. Smith states that he has frequently found the latter firmly united by bone, while the neck of the femur has, after maceration, become loose in the cavity which it had formed for itself between the trochanters. In these cases the bond of union is generally a cartilaginous and fibro-cartilaginous structure of extreme density and great strength, and which, along with the mechanical support resulting from the impaction, enables the patient to bear his weight upon the limb before the osseous

union of the cervix with the shaft has been accomplished. (Op. cit. p. 36.)

In those rare cases of intra-capsular fracture in which union by bone has taken place, it is highly probable, either that the fibrous covering of the neck has remained wholly or partially uninjured, or that the fragments have been impacted or interlocked in the manner described by Mr. R. W. Smith. In either event the fractured surfaces are retained steadily in their position, and are never completely removed from contact with each other. These are precisely the cases, unfortunately, in which the symptoms of the accident are most obscure, and in which the chance of union may be, and probably often is, destroyed or diminished by the too great eagerness on the part of the surgeon to obtain conclusive evidence of the existence of fracture. On the other hand, it is not impossible that union by bone may sometimes have taken place, when the patient has been kept quiet for some time after the accident, in cases where fracture was not suspected, but where the injury has been set down as merely a contusion.

The diagnosis in these cases is often most difficult, for when the muscles around the hip have suffered a violent contusion, the patient is often unable, by a voluntary effort, to raise the injured limb; the inclination of the pelvis produces an *apparent* shortening, and the foot lies everted; there is swelling around the joint, and every motion is attended with pain. Nor does the subsequent progress of the case always tend to remove the uncertainty, for these cases of contusion of the hip are not unfrequently followed, especially in old people, at a period remote from the receipt of the injury, by a *real* shortening of the limb and eversion of the foot—circumstances well calculated to confirm the belief of a fracture of the neck of the femur having been the original injury; whereas these subsequent changes are the result of a slow and mild inflammatory action excited by the contusion in the cancellated tissue of the head and neck of the femur. (*R. W. Smith*, op. cit. p. 30, 31.)

The appearances, occasioned by the alterations which the head and neck of the femur undergo in the disease described by Mr. R. Adams as chronic rheumatic arthritis, present many points of resemblance to fracture of the neck of the femur, and if a patient suffering from this disease should meet with a contusion of the hip, a mistake is especially likely to occur. On the subject of chronic rheumatic arthritis of the hip joint, see *R. Adams, On Abnormal Conditions of the Hip Joint, Cyclop. of Anat. and Physiol.* vol. ii. p. 789; and *R. W. Smith, On Fractures, &c.* p. 113; and JOINTS, DISEASES OF.]

Having spoken of the nature of fractures of the neck of the thigh-bone within and without the capsular ligament, I come next to the consideration of the proper practice to be adopted. In the first description of the injury, as osseous union is rare, ought we to endeavour to keep the fragments as nearly in a state of apposition as possible, and subject the patient to rest and confinement, with the view of promoting the other modes of union, so well pointed out in Dr. Colles's paper? Or should we, as Sir A. Cooper does, avoid confining the patient to any long or continued extension, "as being likely to be productive of ill health, without the probability of producing union?" Yet, it appears both from this gentleman's own statements, and

from those of Dr. Colles, Mr. Langstaff, Mr. B. Bell, and others, that though a bony union cannot always be effected, other connecting means may be established; and the more perfect these are, the less will be the subsequent lameness. So long, therefore, as these facts are incontrovertible, I should be disposed to recommend surgeons to do everything in their power to keep the limb quiet, and in a desirable posture for a due length of time. On this point all surgeons must, on reflection, be unanimous. It is one that I have always insisted upon in my surgical writings, and it is one that is very properly defended by Mr. Amesbury. For this purpose, sometimes Desault's or Boyer's apparatus, with the limb in the straight posture; sometimes the double inclined plane, with the limb in the bent position, and the patient on his back; and sometimes, in America, Hagedorn's ingenious plan of using the sound limb as the part to which the long splint and footboard, with numerous perforations, should be attached, in order that the length of the injured limb, and the right position of it and the foot, may be effectually maintained; are preferred. Sir A. Cooper merely places one pillow under the whole length of the limb, and puts another transversely under the patient's knee, so as to keep the limb in an easy bent position. In a fortnight or three weeks the patient is allowed to sit upon a high chair, and in a few more days he begins to take exercise upon crutches. After a time these are laid aside, a stick substituted for them, and in a few months this assistance may be dispensed with. At the end of the treatment a shoe must be worn with a sole of equal thickness to the diminished length of the limb. (*Surgical Essays*, part ii. p. 50.) On this plan, of course, no bony union can be expected, and I prefer the doctrine of Dupuytren and Langstaff, that full time should be afforded for the chance of osseous union being completed, and efficient means adopted to keep the limb quiet and in the best position. From one hundred to one hundred and forty days are specified by Dupuytren as necessary for the consolidation. (*Clin. Chir.* t. ii. p. 99.)

In the treatment of such fractures of the neck of the femur as are situated on the outside of the capsular ligament, Sir A. Cooper prefers the position in which the patient lies on his back, with the injured limb in a bent posture, supported on what is termed the double inclined plane. When the limb has been placed over this machine in an easy bent position, a long splint, reaching above the trochanter major, is applied to the outer side of the thigh, and fastened to the pelvis with a strong leathern strap, so as to press one portion of bone towards the other. The lower part of the splint is also fastened to the outside of the knee with a strap. The limb is to be kept as quiet as possible for eight weeks, at the end of which time the patient may leave his bed, if the attempt should not cause too much pain; but the splint is to be continued another fortnight. (*Surgical Essays*, part ii. p. 59.)

Dupuytren laid the patient on his back; bent the thigh on the pelvis, and the leg on the thigh. He then reduced the displaced outer fragment. He disapproved of continued and forcible extension; and preferred a double inclined plane, composed of several pillows rolled firmly up into the form of bolsters, placed one above the other, and secured together by stitching. Along this double plane he placed another pillow lengthwise, extending from

the hip to the heel. The leg and thigh were retained in their places by sheets folded round the limb after the manner of a cravat, and fastened to the bedposts. When consolidation had taken place, the double inclined plane was gradually lowered.

In University College Hospital I have, in many cases, successfully employed the double inclined plane with a pelvis strap; but have latterly tried still more extensively the straight position and long splints with equal success, and perhaps more comfort to the patient.

Pott's method of treatment, with reference to these cases, is now entirely renounced. The bad effects and painful consequences of having the whole weight of the trunk operating upon the fractured ends of the bone, which are often not properly in contact, are too obvious to need any comment. Yet this injudicious pressure was made in the position recommended by Pott, which also forbids the use of long effective splints, and all assistance from moderate continued extension.

A fracture of the neck of the thigh-bone may be complicated with a dislocation of the head of the bone. (See *J. G. Haase, De Fracturâ Colli Ossis Femoris, cum Luxatione Capitis ejusdem Ossis conjuncta.* Lips. 1798.)

[*Oblique fracture through the trochanter major, without injury to the neck of the bone.*—In this somewhat rare form of injury the fracture has an oblique direction downwards and inwards, so as to separate the upper part of the trochanter major, together with the head and neck, from the shaft of the femur. Sir Astley Cooper has given several examples of this fracture; in one of which the nature of the injury was verified by post-mortem examination. Another instance, similarly confirmed, has been related by Mr. Stanley. (See *Med. Chir. Trans.* vol. xiii.)]

In this fracture, according to Sir A. Cooper, the leg is very little, and sometimes not at all, shortened; the foot is benumbed; the patient cannot turn in bed without great difficulty and pain; in some cases the detached portion of the trochanter is drawn forwards towards the ilium; in others, it falls towards the tuberosity of the ischium; but, in general, it is widely separated from that portion which remains connected with the neck of the bone, so that the finger may be placed between the fractured portions. The foot is considerably turned outwards, and crepitus is with difficulty discovered if the trochanter is either much fallen or much drawn forwards. This fracture unites very firmly and more quickly than when the cervix is broken at the root of the trochanter, and the patient recovers with a very good use of his limb. (*On Dislocations*, B. Cooper's ed. p. 175.) [Usually there is little or no diminution in the length of the limb; but, says Sir A. Cooper, when the fracture happens below the insertion of the principal rotatory muscles, the lower portion of bone is much raised by the action of the glutæus maximus, and the limb becomes very much shortened and deformed at the place of union by exuberant callus. This allusion to the rotator muscles is not very intelligible; the presence or absence of shortening is much more likely to depend upon the direction of the line of fracture. If this is very oblique *downwards*, the glutæus maximus may readily draw upwards the shaft of the bone, while if it passes more *inwards*, or at all approaches to the horizontal line, it will

be very difficult for the fractured surfaces to become clear of each other, so as to allow shortening to take place. The case recorded by Mr. Stanley is interesting, from its presenting some striking points of resemblance to a dislocation of the hip. The limb was shortened three-quarters of an inch and slightly everted. The extremity of the shaft of the femur was in its natural situation, but behind it, and a little distance from it, a *bony prominence was discovered resting on the ilium, towards the great ischiatic notch, strongly resembling the head of the femur.* This prominence, as was proved at the post-mortem examination, was occasioned by the posterior and larger portion of the trochanter, which was drawn backwards towards the ischiatic notch. (*Med. Chir. Trans.* vol. xiii.)

The treatment of the fracture through the trochanters may be conducted on the same principles as that of fracture of the neck of the femur. Most surgeons would probably prefer moderate continued extension by means of the long straight splint, while the fracture may be steadied by a broad belt buckled round the pelvis. If the upper part of the trochanter should be inclined backwards, which appears to be frequently the case, an attempt should be made to remedy the displacement by pressing it forwards, if possible, with the fingers, and then supporting it by placing a thick pad behind it, underneath the pelvic band.

Fracture of the trochanter major, by which this process is broken off without further injury to the neck or shaft, occasionally occurs. Sir A. Cooper relates a case, the particulars of which were sent to him by Mr. Aston Key, occurring in a girl æt. sixteen, in which this process was broken off at the point at which it is naturally united as an epiphysis. The patient had fallen in crossing the street, and struck her trochanter violently against the curb stone. She arose and walked home without much pain or difficulty; but four days afterwards, in consequence of the increase of pain she experienced, she applied for admission to Guy's Hospital. The injured limb was considerably everted, and apparently about half an inch longer than the other. It admitted of passive motion in all directions, but in abduction gave her considerable pain. She had perfect command over all the muscles except the rotators inwards. No crepitus or displacement of bone could be detected. She died of fever a few days afterwards, and the examination of the part showed a fracture which had detached the trochanter from the head and neck of the bone, but without tearing through the tendons attached to the outer side of the process. The tendons, those of the two smaller glutæi, so effectually prevented all motion of the fractured portion, that when dissected from the body not the least motion could be produced except in one direction—upwards and downwards.

Another case in which this injury was presumed to have occurred, is related by Mr. Bransby Cooper. The patient was thrown out of his gig, and fell upon the trochanter major. He was unable to walk, but could bear his own weight on the limb of the injured side. The trochanter major was not perceptible in its usual position, and pressure in this situation was extremely painful to the patient. By bending the pelvis towards the injured side, and at the same time abducting the limb to its fullest extent, and pressing down the glutæi muscles, the detached portion of bone could be depressed, and

crepitus was produced. Mr. Cooper endeavoured to keep the fractured portions of bone in apposition, by applying bandages and compresses upon the upper portion of the trochanter, so as to draw it downwards and fix it in its place, and he was kept in bed in this position for more than six weeks. Two years afterwards he was seen by Mr. Cooper, and there was then some degree of lameness remaining, but he was capable of performing most of the functions of the injured hip, even to slight feats of agility, though with a halt. (See *Sir A. Cooper, On Dislocations*, edited by B. Cooper, p. 185.) Another instance is mentioned by Mr. Stanley, and two others by Dr. Hamilton, in which this fracture is supposed to have occurred, although he thinks it not improbable that they may have been examples of impacted fracture of the neck. (See his *Treatise on Fractures and Dislocations*, p. 390, Philadelphia, 1860.)

In the treatment of such cases, says Sir A. Cooper, there must always be great difficulty in producing and maintaining coaptation of the parts; and the prognosis of perfect recovery must be unfavourable, for the fractured portion of the trochanter being covered by the tendons of the glutæi muscles, and by the synovial lining of a bursa, and invested with tendons and not with periosteum, and being separated from its right position by the muscles, is placed under circumstances similar to the patella, olecranon, and os calcis, and, like these bones, when entirely severed by fracture, cannot be capable of reparation by ossific union.]

Fractures of the Shaft of the Femur.

The shaft of the thigh-bone is liable to be broken at any point; but it is in the middle third of this extent that fractures mostly occur, which are sometimes transverse, but more frequently oblique. The latter direction of the injury makes a serious difference in the difficulty of curing the case without future deformity or lameness. Sometimes the fracture is comminuted, the bone being broken in more places than one; and sometimes the case is attended with a wound, communicating with the fracture, and making it what is termed *compound*. As Petit remarks, however, the thigh-bone is less seldom broken into several pieces than other bones more superficially situated. [Fractures of the femur are not unfrequent in children, in whom they are more common than fractures of the leg, whereas the reverse is the case in the adult.]

A fractured thigh is attended with the following symptoms: acute pain at the instant of the accident; a sudden inability to move the limb; a preternatural mobility of one portion of the bone; a distinct crepitus, if the two ends of the fracture rub against each other; deformity, in regard to the length, thickness, and direction of the limb. The latter change, viz. the deformity, ought to be accurately understood; for, having a continual tendency to recur, especially in oblique fractures, the chief difficulty in the treatment is to prevent it. (*Desault, par Bichat, t. i. p. 181.*)

Almost all fractures of the thigh are attended with deformity. When this is considered, in relation to length, it appears that, in oblique fractures, the broken limb is always shorter than the opposite one; a circumstance denoting that the ends of the fracture ride over each other. We may also easily convince ourselves, by examination, that the deformity is owing to the lower end of the fracture having ascended above the upper one, which remains stationary.

For the purpose of exemplifying the power of the muscles to displace the ends of the fracture, mention is made, in Desault's works, of a carpenter who fell from a scaffold and broke his thigh. The limb, the next day, was as long as the other; but the man had a complete palsy of his lower extremities, and could not discharge his urine. The moxa was applied, the muscles soon regained their power, and then the shortening of the limb began to make its appearance.

Besides the action of muscles, there is another cause of displacement. However firm the bed may be on which the patient is laid, the buttocks, more prominent than the rest of the body, soon form a depression in the bedding, and thence follows an inclination in the plane on which the trunk lies, which, gliding from above downward, pushes before it the upper end of the fracture, and makes it ride over the lower one. The muscles, irritated by the points of bone, increase their contraction, and draw upward the lower part of the bone; and from this double motion of the two ends of the fracture in opposite directions, their riding over each other results.

Transverse fractures are less liable to be displaced in the longitudinal direction of the bone, because, when once in contact, the ends of the fracture form a mutual resistance to each other; the lower end, drawn upward by the muscles, meets with resistance from the upper one, which

being itself inclined downward by the weight of the trunk, pushes the former before it, and thus both retain their position in relation to each other.

The deformity of a fractured thigh, in the transverse direction, always accompanies that which is longitudinal; but sometimes it exists alone. This is the case when, in a transverse fracture, one end of the bone is carried outward, the other inward; or one remains in its place, while the other is separated. The upper end of the fracture is not now, as in the foregoing instance, motionless in regard to the muscular action; for the contraction of the pectineus, psoas, iliacus internus, and upper part of the triceps, draws it from its natural direction, and contributes to displace it.

The deformity of the limb, in regard to its direction, is either the consequence of the blow which produced the fracture, or, what is more common, of the ill-directed exertions of persons who carry the patient. Thus, an injudicious posture will bend the bone so as to make an angle.

Whatever may be the kind of deformity, the lower end of the fracture may retain the natural position in which it is placed, or else undergo a rotatory motion on its axis outward, which is very common, or inward, which is more unusual. This rotation always aggravates the displaced state of the fracture, and should be attended to in the reduction. (*Desault, t. i. p. 180, 185.*)

[*Fractures in the upper third of the shaft*, or just below the trochanter minor, are especially subject to distortion. According to Sir A. Cooper, the upper end of the broken bone is drawn forwards and upwards, so as to form nearly a right angle with the body, and the cause of this position is evidently the contraction of the iliacus internus and psoas muscles, assisted by the pectineus, and perhaps by the first head of the triceps. (*On Dislocations, &c. B. Cooper's edition, p. 190.*) M. Malgaigne has questioned the correctness of Sir A. Cooper's statement. According to him, it is an angular displacement *outwards* rather than forwards which really takes place; and he attributes it to the action of the powerful muscles on the internal part of the thigh, which represent the cord of an arc formed by the neck and shaft of the femur. When the arc is broken, these muscles act so as to approximate the extremities without encountering any resistance. On the contrary, the muscles which are inserted into the great trochanter only favour the movement of abduction which carries the superior fragment outwards.—He has never seen the displacement forwards carried to the extent indicated by Sir A. Cooper and Boyer, and believes that it is often absent altogether, or that when present it is only slightly marked, and in combination with the displacement outwards.

Fracture just above the condyles of the femur sometimes happens, and, according to Sir A. Cooper, is usually oblique from behind downwards and forwards. The appearances produced by it are that the lower and broken extremity of the shaft of the bone projects, and forms a sharp point just above the patella, which pierces the vasti muscles and threatens to tear the skin, and sometimes does so; whilst the patella, tibia, and condyles of the femur sink into the ham, and are drawn upwards behind the broken extremity of the shaft of the os femoris. The accident is likely to happen when a person falls from a considerable height upon his feet, or is

thrown upon the condyles of the os femoris with the knee bent. (*On Dislocations, B. Cooper's edit.* p. 244.) M. Malgaigne has more frequently found fracture in this situation caused by direct violence, and taking a transverse instead of an oblique direction, though he admits that when it is caused indirectly, in the way Sir A. Cooper describes, it is more frequently oblique. In young persons a separation of the epiphysis may take place. In a case of this kind in a child eleven years old, mentioned by Malgaigne, the superior fragment was carried backwards, and after amputation it was found that the condyles were placed in front of the shaft of the bone, and turned so that their articular surface looked forwards.]

Treatment.—Three very different methods of treating fractured thighs are followed. In one, which was recommended by Hippocrates, and is preferred by a vast number of surgeons, the limb is kept in the straight or extended position. In another, the limb is laid upon its side, with the knee bent; a mode which was extolled by Pott, and has had many partisans in this country. To these two positions for fractured thighs is to be added that in which the patient lies upon his back, with his thigh and leg in the bent position, supported on two oblique planes, or surfaces, the apex or angle of which is beneath the ham.

That Pott lost sight of certain advantages of the straight position; that he was blind to the imperfections of the bent posture; and that he exaggerated the power, which we have, of relaxing all the muscles of a limb by position; few reflecting surgeons of the present day will be inclined to deny. Were we to believe the literal sense of several passages in Pott's Remarks upon Fractures, we should suppose it practicable to relax at once, by a certain posture of the limb, every muscle connected with a fractured bone. In the first vol. of his works, page 389, edit. 1783, he observes, in speaking of what must best answer the purpose of incapacitating the muscles from displacing the fracture: "Is it not obvious that putting the limb into such position as shall relax the whole set of muscles belonging to, or in connexion with, the broken bone, must best answer such purpose?" and, in the next page, "What is the reason why no man, however superficially acquainted with his art, ever finds much trouble in setting a fractured os humeri? is it not because both patient and surgeon concur in putting the arm into a state of flexion, that is, into such a state as relaxes all the muscles surrounding the broken bone?" Also, in page 393, he continues, "Change of posture must be the remedy, or rather, the placing the limb in such manner as to relax all its muscles." Putting out of present consideration the disputed point, whether the relaxed state of a muscle is really the most efficient for the prevention of those spasms which displace a fracture, and occasion vast suffering (see *J. Houston, in Dublin Journ. of Med. Science*, vol. viii. p. 459), the possibility of perfectly relaxing all the muscles of the limb by any position, so long as different muscles have different uses, different situations, and different attachments to the bones, every one must grant to be only a visionary project. For instance, do not the patient and surgeon, in the case of fractured os humeri, adverted to above, concur in putting the fibres of the triceps and anconeus into a state of tension, at the same moment that they relax the biceps and brachialis anticus.

The position of the fractured os femoris, says Pott, should be on its outside, resting on the great trochanter; the patient's whole body should be inclined to the same side; the knee should be in a middle state between perfect flexion and extension, or half-bent; the leg and foot, lying on their outside also, should be well supported by smooth pillows, and should be rather higher in their level than the thigh; one very broad splint of deal, hollowed out and well covered with wool, rag, or tow, should be placed under the thigh, from above the trochanter, quite below the knee; and another, somewhat shorter, should extend from the groin to below the knee on the inside, or rather in this posture on the upper side. The bandage should be of the eighteen-tail kind; and when the bone has been set, and the thigh well placed on the pillow, it should not, without necessity (which necessity in this method will seldom occur), be ever moved from it again until the fracture is united; and this union will always be accomplished in more or less time, in proportion as the limb shall have been more or less disturbed.

Here only two splints are mentioned; but the few surgeons who still adopt this method usually employ four. After placing the patient in the above position, the necessary extension is to be made. Then the under splint, having upon it a broad soft pad, and an eighteen-tailed bandage, is to be laid under the thigh, from the great trochanter to the outer condyle. The surgeon, before laying down the tails of the bandage, and putting on the other three splints, is to take care that the fracture lies as evenly as possible.

In the foregoing observations, we find Pott directing the leg and foot to be rather higher in their level than the thigh; with what particular design, I have not myself been able to make out. Whoever meditates upon the consequence of elevating the leg and foot above the level of the thigh, in the bent position, will know that it is to twist the condyles of the os femoris more outward than is natural. When a patient is placed, according to Pott's direction, upon a common bed, the middle soon sinks so much that the leg becomes situated considerably higher than the thigh, and I am disposed to think that this is one cause why so many broken thighs were formerly united with the foot permanently distorted outward. Fractured thighs should always be laid upon beds not likely to sink much. When this happens, no rational dependence can be put in the efficacy of the bent position, and, as Desault has explained, the same thing is hurtful also in the straight posture.

Pott's position certainly leaves the leg and foot too movable and unsupported, and, though it may relax the muscles which have the greatest power to disturb the coaptation of a fractured thigh, it leaves a mass of muscle unrelaxed, quite sufficient to displace the ends of the bone. Hence, practitioners should endeavour to improve the apparatus employed, so that it may make a permanent resistance to the action of the muscles, and in the straight position such resistance may undoubtedly be made to operate with most effect and convenience.

In the early editions of this Dictionary, I expressed a preference to Pott's method of treating broken thighs. More experience, however, made me a convert to the sentiments of Desault on this subject. The terrible compound fractured thighs which I had under my care in the campaign in

Holland in the year 1814, could not have been at all retained by any apparatus put merely upon the thigh itself. The superiority of long splints, extending the whole length of the limb, was in these cases particularly manifest. With such splints, which maintain steady the fracture itself, the knee, leg, ankle, and foot, the patient may, in fact, even be removed upon an emergency from one place to another, without any considerable disturbance of the broken part. But how could this be done in Pott's position, with short splints, merely applied to the thigh, affording no support to the leg, and not confining the motions of the knee and foot?

It was observed by Desault, that, if we compare the natural powers of displacement with the artificial resistance of almost every apparatus, we shall find that the disproportion between such forces is too great to let the former yield to the latter. The action of the muscles, however, which is always at first very strong, he conceived might afterwards be gradually overcome by extension being kept up.

A power incessantly operating can effect what another greater power, temporarily applied, cannot at once accomplish, and the compression of circular bandages tends also to lessen the force of the muscles.

Desault cured an immense number of fractured thighs without any kind of deformity. This success was chiefly ascribed to the well-combined employment of extension and compression of the muscles. The advantage of keeping the muscles a long while extended, in order to diminish their power, seemed to him particularly evident in the reduction of certain dislocations, as those of the shoulder, in which we often cannot succeed till the muscles have been kept on the stretch for a greater or lesser time. The fracture of the patella and olecranon equally demonstrates the utility of compression for the same purpose; as, when the muscles are not steadily compressed by the bandage, they draw upward the fragment of bone with double or triple force.

To the treatment of fractured thighs in the bent posture, Desault entertained the following objections: the difficulty of making the extension and counter-extension when the limb is so placed; the necessity of then applying them to the fractured bone itself, instead of a situation remote from the fracture, as, for example, the lower part of the leg; the impossibility of comparing with precision the broken thigh with the sound one, in order to judge of the regularity of its shape; the irksomeness of this position long continued, though it may at first seem most natural; the inconvenient and painful pressure of a part of the trunk on the great trochanter of the affected side; the derangement to which the limb is exposed when the patient has a motion; the difficulty of fixing the leg firmly enough to prevent the effect of its motion on the thigh-bone; the manifest impossibility of adopting this method when both thighs are fractured; the unfavourable results of the trials of such posture made in France; and, what is gained by the relaxation of some muscles, is lost by the tension of others.

According to Desault, an apparatus which does not execute permanent extension may suffice for transverse fractures; but is always ineffectual when the division is oblique, because it does not fulfil the twofold indication of drawing downward the lower end of the fracture, and keeping the other one upward. He inculcated that the object par-

ticularly to be aimed at was such a disposition that the foot, leg, thigh, and pelvis should constitute but one whole; so that, though the different parts thereof might be drawn in different directions, yet they would still, with respect to one another, preserve the same mutual relation; and he invented the following apparatus to answer these purposes. A strong splint, long enough to extend from the crista of the os ilium to a certain length beyond the sole of the foot, and rather more than two inches and a half broad, with each of its extremities pierced in the form of a mortise, and terminating in a semicircular niche, is a principal part of Desault's apparatus. It is applied to the exterior side of the thigh, by means of two strong linen rollers, each more than a yard long. The middle part of one roller is applied to the inside of the thigh at its upper part; its ends are brought to the exterior side of the thigh, passed through the mortise, and knotted on the semicircular niche. Pads are to be previously placed under its middle part, in order to prevent any disagreeable pressure; as well as on the tuberosity of the ischium, which Desault considered as the principal point of action of this band. The inferior part of the leg is next covered with pads, on which the middle part of the second roller is placed, the extremities of which cross on the instep and upper part of the foot, then on the sole; after which they are conveyed outward, and one end passed through the mortise, and knotted with the other on the niche, with such a degree of force as to pull the inferior portion of the femur downward, and push the splint upward, and by this means, the pelvis, and superior portion of the fractured bone. On the internal side of the limb is placed a second splint, which extends from the superior part of the thigh to a certain distance beyond the foot. A third is placed on the anterior part of the limb, from the abdomen to the knee. The superior extremities of the anterior and exterior splints are fixed by means of a bandage passed round the pelvis. A roller, the middle part of which is placed under the sole of the foot, and the extremities crossed on its superior surface, and fastened to the splints, operates with them in preventing the foot from moving.

Before applying the apparatus, Desault covered the whole limb with linen, wetted with a solution of the acetate of lead. Over these, Scultetus's bandage was put, and a roller round the foot, all wetted with the same lotion. (*See Parisian Chir. Journal*, vol. i. *Œuvres Chir. de Desault*, par Bichat, t. i. *Rosalino Giardina, Memoria sulla Fratture, con alcune Modificazioni all' Apparato di Desault*. 8vo. Palermo, 1814. *Boyer, Maladies Chir.* t. iii.)

In University College Hospital, Desault's method somewhat modified, and in particular without the employment of the wetted many-tailed bandage, is commonly preferred. Dr. Houston, who is an advocate for the same practice, has lately published some interesting cases and observations relative to the treatment of fractures generally, and in particular to the question concerning the advantages of one kind of posture over another. Dr. Houston conceives that they will tend to settle what is the best mode of preventing early spasms, pain, and fever, and of securing for the patient, after the cure, the most seemly and useful condition of the limb; whether that of leaving the broken bone, during the first day, in the predicament in which it has been

thrown by the accident, or that of bringing about, and securing, by artificial means, the proper apposition of the fragments, is the more likely to accomplish these objects. He believes also, that they will enable us to draw a comparison between the advantages of the flexed and straight postures. It appears to him that no advantage whatever is gained by leaving the ends of a broken bone in any manner out of place. The excuse for this practice, founded on the doctrine of relaxing the muscles to prevent or relieve spasms, he regards as completely erroneous; and he insists upon the fact, that relaxation of the muscles which have a tendency to spasmodic contraction, excites and promotes it; whilst, on the other hand, extension, or stretching of the same muscles, is the most likely means of averting or subduing the spasm. In the spasmodic action of the gastrocnemius, which follows over-exertion of it, he observes, relief is sought in an attempt at elongating the muscular fibres by stretching out the heel. A person in bed seized with such cramps, will press the heel of the affected limb against the footboard, or get out of bed, in order to accomplish more effectually the same object, by standing with the heel on the ground. In this case, says Dr. Houston, it is obvious that the relaxation of the muscle is favourable to the occurrence of spasm, and that extension constitutes a means of relief. The primary cause of spasms of the muscles in fractures he conceives to be the loosening of one or other of their fixed points of attachment; and he thinks it not likely that by leaving them in the loosened state, or by giving one set of muscles a greater degree of relaxation than another, a check will be given to irregularity in their movements. On the contrary, it appears to Dr. Houston, both from an examination into the laws of muscular contraction, and from observations of the phenomena which occur in other cases of disease, as well as in fractures, that the more completely the muscles are extended in length, and secured by their extremities to unyielding points, the less will be their disposition to spasmodic action. The practice of placing a broken limb in the bent posture does not appear to Dr. Houston the most calculated to avert or check spasms; for, by such posture, the most powerful set of muscles, the flexors, seem to him to be brought into a condition "favouring the energy of their contraction;" whilst the influence of the extensors, in counteracting the effects of such contraction, is weakened nearly in the same degree.

Moderate soft pressure on the surface of a fractured limb, appears to Dr. Houston to assist in the prevention of cramps in the long muscles, "on the same principle, that proper fixtures for the attachment of their distal extremities contributes to that effect. Such pressure may exert its beneficial influence in controlling any irregular action in the muscles by numbing their sensibility, and producing in them a certain amount of fatigue which weakens their powers of contraction, as well as by propping together, and keeping steady the broken fragments of the bone." (See *Dublin Journ. of Med. Science*, vol. viii. art. 19.)

Dr. Houston's views of the physiology of muscular action, with reference to fractures of the extremities, make him an advocate for the extended posture, accompanied, if necessary, with extension. The cases which he has published are brought forward to prove the efficacy of this practice in

preventing the occurrence of spasms, inflammation, and fever; and some of them to exemplify its utility even when circumstances have prevented its adoption until after the coming on of these symptoms. Dr. Houston finds that the patient "becomes sooner reconciled to the bed in this posture, than in the flexed one; he can be shifted more readily, so as to vary the points of contact between his body and the bed, and thereby save himself from excoriations, or sloughing of any part; and he can assume the sitting posture, and maintain it with less fatigue, for a considerable time. A better judgment may be formed of the length and shape of the broken limb, by its admitting of a comparison with the sound one; the limb can be kept more steady; and extension, if necessary, can be more readily and effectually practised." (*Houston*, vol. cit. p. 489.)

The *double-inclined plane* does not appear to Dr. Houston exempted, in any considerable degree, from the ordinary inconveniences attendant on any other plan of treatment, which has for its object the principle of relaxation, or flexure of the limb; "whilst it is almost totally useless, as a means either of effecting elongation of a shortened bone, or of giving, in many cases, steady support to the member. Besides, it throws the weight of the body so completely on one part of the buttock, and by its bulk and shape so deprives the patient of the means of relieving himself from such injurious pressure, that excoriation and sloughing of the hips are frequent consequences of its use." (p. 490.)

Dr. Houston also objects to the double-inclined plane for fractures of the thigh, because it has no provision "by which the upper fragment may be steadied against the lower, especially in cases where the lesion in the bone has taken place near the trochanters. The lower piece, together with the knee and leg, are immoveably fixed, whilst the upper is left in such a predicament that the least movement of the buttocks bends it from side to side, and rubs and twists its broken surface against that from which it has been detached. There is no provision in the inclined plane by which the upper part of the thigh, when bent upon the pelvis, can be secured against the motions communicated to it by that part, such as may be effected in the extended posture by long splints and pads passing up on the inside close to the perineum, and on the outside, as far along the body as may be thought necessary, securing thereby all the parts, so that, in any movement which is made, all must go together, as if they were one solid piece." (Vol. cit. p. 492.)

The usual objections to the straight posture in fractures just below the trochanters, on account of the tendency of the upper fragment to be pulled forwards by the psoas and iliacus muscles, were not exemplified in one of the cases of this description, the particulars of which are given by Dr. Houston. "The projection forwards of the upper piece, so remarkable in the first days after the accident, gradually subsided, under gentle pressure on the forepart of the thigh, and the bones finally assumed their natural points of connexion with each other. By the adoption of the extended posture, with the aid of extension, that deformity, so common in fractures of the thigh, permanent eversion of the toes, and I believe also that of shortening of the limb, will be more probably averted than can be done under the best directed

efforts of the double-inclined plane." By the same plan, likewise, Dr. Houston observes that pain and excoriation of the heel may be easily prevented if a narrow pad be laid between the limb and bed, a little above the heel. The apparatus which this gentleman employs for fractures of the lower extremities, is a modification of that recommended by Desault, and consists of a tailed bandage, two long lateral splints, and splint-cloth, two calico bags containing bran, and broad straps with buckles, together with a footboard, and if necessary, lacs of calico for the purposes of extension. "The tails of the bandage may be two inches and a half broad, and about two feet long. They should be applied neatly around the limb, with due regard to lightness. The application of this bandage tends to steady and support the muscles, and, if much inflammation be present, it may, when very lightly applied, be of use in conveying discutient washes. In a case of compound fracture, the bandage may be left out to facilitate the discharge of matter, and to permit the application of poultices or dressings, without disturbing the other parts of the apparatus. The splints may be made of deal, of sufficient thickness to prevent their bending, and from $2\frac{1}{2}$ to $3\frac{1}{2}$ inches in breadth, according to the thickness of the limb to which they are to be applied. They should be of equal breadth, as otherwise the limb will turn to the side of the narrow one. In case of necessity for permanent extension, the external splint should be made, as directed by Desault, with a hole and notch at either end, by which to fasten the lac; and it will be advantageous here to have this splint of sufficient length to mount well up along the side of the abdomen, as the higher the point to which the lac is fastened the more effectually will the extension be exerted in the axis of the limb." Dr. Houston prefers pads of linen, or calico, filled with bran, and about one-third broader than the splints. If permanent extension be necessary, the upper lac, or band for counter-extension, he recommends to be filled in a baglike form with bran, in order to prevent excoriation of the groin. The ends of this lac should be long enough to be carried round the abdomen, after being fastened to the top of the splint, by which means the splint will be effectually secured to the side. In order that the extension of the lower end may be made as much as possible in the line of the axis of the limb, Dr. Houston deems it advantageous to draw the lac through a hole or slit in the centre of the footboard, which will thereby serve as a pulley to give the lac a perpendicular direction, before it is turned towards the extremity of the outer splint, to which it is to be fastened. A piece of leather, introduced between the ankle and the lac, will save the skin from the injurious effects of pressure. The lac may consist of a long strip of calico, doubled up several times into a breadth of about an inch and a half, and smoothed so as to make it lie flatly. The mode of its application may be that usually practised for the reduction of dislocations, by which extension is made equally from both sides of the limb. For other particulars, the reader is referred to Dr. Houston's paper. (See *Dublin Journ. of Med. Science*, vol. viii. art. 19.)

Thus we find that Dr. Houston's principles and practice, in relation to fractures of the thigh, are as opposite as possible to those of Pott, and coincide very closely with those of Desault. As no

posture will hinder the muscles from displacing the ends of the fracture, I have always recommended that to be generally preferred in which the most efficient mechanical aid can be employed. The position chosen by Pott I have therefore long abandoned, and tried sometimes a slightly flexed position, on a well-made double-inclined plane, with footboard, and pelvis, and thigh-straps; but of late still more frequently the straight position. During the first year after the opening of University College Hospital, I tried both plans promiscuously, and nearly every case terminated without deformity; but as the patients in the straight position appeared to suffer least inconvenience, I have since commonly preferred it. With regard to Dr. Houston's observation, that the double-inclined plane cannot be made to "bind the pelvis and broken fragments together as one piece, only moveable together," it cannot apply to one of proper construction, like that of Amesbury, with a pelvis and thigh strap. I have now a woman under my care in University College Hospital, whose thigh-bone is broken close below the trochanter minor. The extended position was tried for the first few days; but as the upper fragment continued to project considerably forwards, the slightly flexed posture, on a double-inclined plane, with a pelvis strap, was adopted; and the ends of the fracture were then kept together without difficulty; and the union of them has taken place very favourably.

Fractures of the femur, near the knee, are recommended by Sir Astley Cooper to be treated in the extended position, with lateral splints.

Instead of the position advised by Pott, or that recommended by Desault and Boyer, some surgeons prefer the posture in which the patient lies upon his back, with the limb supported in the bent attitude by means of a wooden frame. This machine, in its most simple form, consists merely of boards, ten or eleven inches in breadth, one reaching from the heel to the ham, the other from the ham to the tuberosity of the ischium. Under the knee-joint they are united at an angle, while a horizontal board connects their lower ends together. Thus they form two sloping surfaces, to which cushions are adapted, and over which the limb can be placed in an easy bent position. Near the edge of the inclined boards holes are made, furnished with pegs. After the bone has been set a long splint is applied from the hip to the side of the knee, and another along the inside of the thigh. (See *Sir Charles Bell's Operative Surgery*, vol. ii. p. 189.) The foregoing apparatus does not sufficiently secure the leg and foot from motion, though, with the aid of a roller and a footboard, this advantage might easily be obtained. At present, therefore, the oblique planes of Amesbury and M'Intyre are generally preferred, which are more complete, admit of being placed at any angle, and fulfil their purpose with greater efficiency, particularly when the pelvis and thigh straps are employed. Indeed, whatever apparatus be applied, or whatever posture be chosen, the pelvis strap is a most important thing if the fracture be high up; and without its assistance, as Dupuytren justly remarks, the patient cannot be cured without deformity. (*Clin. Chir.* t. i. p. 333.) The fracture bed, devised by my friend Mr. Earle, is excellently calculated for this mode of treatment, and has a contrivance by which the patient is enabled to have stools without moving himself or changing his posture in the slightest

degree. (See *Earle's Practical Obs. in Surgery*, p. 125, &c. 8vo. Lond. 1823.)

[For a detailed account of the various modifications which have been devised in the long splint, and also in the double inclined plane, see *Dr. Hamilton, Treatise on Fractures, &c.*

The long splint is employed very generally in this country, both in hospital and private practice. Mr. Erichsen, however, states that he has treated many fractured thighs, both in adults and children, by means of the starched bandage, without confinement to bed for more than three or four days, and without the slightest shortening or deformity being left. The following is the plan which he recommends:—A dry roller should be applied to the whole of the limb evenly and neatly, which must then be covered with a thick layer of wadding; a long piece of strong pasteboard, about four inches wide, soaked in starch, must next be applied to the posterior part of the limb, from the nates to the heel. If the patient is very muscular, and the thigh large, this must be strengthened, especially at its upper part, by having slips of bandage pasted upon it. Two narrower strips of pasteboard are now placed along either side of the limb, from the hip to the ankle, and another shorter piece on the fore part of the thigh. A double layer of starched bandage should now be applied over the whole, with a strong and well-starched spica. It should be cut up and trimmed on the second or third day, and then re-applied in the usual way. The points to be especially attended to are that the back pasteboard splint be very strong, at the upper part especially, and that the spica be well and firmly applied, so that the hip and the whole of the pelvis be immovably fixed. (*Science and Art of Surgery*, ed. 3, 1861. p. 247.) Most surgeons will, we think, be reluctant to trust to the starched apparatus, to retain the fracture in apposition from so early a period, though it may be used with advantage after a lapse of three or four weeks. When the fracture is oblique, which in the adult is most frequently the case, it is very difficult, even with the advantage of permanent extension carefully and systematically kept up, to prevent some over-riding of the fractured ends, and consequent shortening of the limb. M. Malgaigne is of opinion that, unless the fracture is transverse, and the displaced fragments can be brought together end to end, so as to oppose themselves to the action of the muscles, it is impossible to preserve to the limb its normal length, whatever apparatus or method may be applied. (*Traité des Fract. &c.* t. i. p. 723.) Many other surgeons of experience have expressed a similar opinion. Dr. Mason Warren, of Boston, U.S., says: "I have never yet seen an oblique fracture of the thigh in a patient over seventeen years of age, in which there was not some shortening. I have had cases shown to me, in which it was averred that the limb was not shortened, but on measuring myself I have found the fact otherwise." In children, however, he believes that union without shortening may be accomplished. According to Dr. Buck, of seventy-four cases of fractured femur of all ages, occurring in the New York Hospital, only nineteen resulted without any shortening, a proportion of about one-fourth. The average shortening of the remaining fifty-five fractures was a fraction less than three-fourths of an inch. (See *Hamilton, On Fract.* p. 400.)

In treating a fractured thigh, with the long

splint or any of its various modifications, great care and attention is requisite, from day to day, to see that no slipping or relaxation of the bandages has taken place. In the application of the bandages it is necessary to protect, with layers of cotton wool, those points on which the extending force must principally operate. From inattention to these points, patients often endure much unnecessary suffering from excoriation or even sloughs on the instep and ankle, and on the heel, if the weight of the limb be allowed to rest upon this part. The perinæum also requires to be well protected by cotton wool or soft pads, from the pressure of the counter extending force. If the case is properly looked after, it is quite possible to continue the apparatus for five or six weeks, without any excoriation or even soreness of the parts mentioned. Mr. Butcher's modification of the long splint is well calculated to keep the limb steady, and to prevent inversion or eversion of the foot, and also to protect the heel from pressure. (See *Dublin Journal of Med. Science*, vol. xxv. 1858, p. 271.)]

Fractures of the Condyles of the Femur.

[Oblique fracture of the external or internal condyle of the femur into the knee joint occasionally happens, but it is a rare form of injury. M. Malgaigne states that he has seen three cases of this nature, but he could only meet with three other recorded examples. Of these six, three were fractures of the internal, and three of the external condyle. Three others, two of the external and one of the internal condyle, are mentioned by Dr. Hamilton in his work *On Fractures and Dislocations*. They may be caused by a fall on the knee, or a direct blow, such as the kick of a horse, or a heavy weight falling upon the condyles. In one case, mentioned by Dr. Hamilton, the patient, a young man, æt. twenty-one, suddenly twisted his knee while undressing himself to bathe, and a fracture of the external condyle was produced. Six months afterwards the separated fragment, comprising a considerable portion of the articular surface, was removed through an incision below the condyle, and the patient recovered.]

The symptoms are severe pain and great swelling of the joint. If the swelling be not too great on examination of the lower end of the femur, the fractured portion may perhaps be felt separated from the rest of the bone, and on pressing the surfaces together crepitus will be elicited. M. Malgaigne states that in general the fractured condyle has a tendency to ascend above the level of the other, and to draw the tibia with it. The leg is therefore abducted upon the thigh in fractures of the external, and adducted in fractures of the internal condyle; or if it does not assume one of these positions spontaneously, movements in one or other of the directions indicated may readily be communicated to it to an abnormal extent.]

In these cases, Sir A. Cooper prefers the straight position, because the tibia presses the extremity of the broken condyle into a line with that which is not injured. The limb is to be put in the extended posture upon a pillow, and evaporating lotions and leeches are to be used for the removal of the swelling and inflammation. "When this object has been effected, a roller is to be applied around the knee, and a piece of stiff pasteboard, about sixteen inches long, and sufficiently wide to extend entirely under the joint, and to pass on each side of it, so

as to reach to the edge of the patella, is to be dipped in warm water, and applied under the knee, and confined by a roller. When this is dry, it has exactly adapted itself to the form of the joint, and this form it afterwards retains, so as best to confine the bones. Splints of wood or tin may be used on each side of the joint; but they are apt to make uneasy pressure. In five weeks, passive motion of the limb may be gently begun, to prevent ankylosis." (*Surgical Essays*, part ii. p. 101; also *Treatise*, p. 221.)

[M. Malgaigne prefers a slightly flexed position of the knee, as less likely to be followed by the articular rigidity, which is especially to be feared as the result of these fractures. The tendency to adduction or abduction of the knee must be guarded against if necessary, by the employment of straight lateral splints.

Sometimes there is a fracture in an oblique or vertical direction, separating the condyles from each other, and communicating above with a transverse fracture of the lower end of the shaft of the femur. When this is the case there is greater mobility than in the fracture last described, and sometimes shortening of the limb from the descent of the shaft of the femur in front of the condyles. The fracture above the condyles has usually an oblique direction downwards and forwards, which favors this species of displacement. The vertical fracture may separate the condyles into equal or unequal portions. Mr. Erichsen mentions a case in which the condyles of *both* femora were splintered into a number of fragments, amongst which the shafts were *impacted*. Excellent union, however, took place, the skin having been uninjured. (*Science and Art of Surg.* ed. 3, p. 249.)

The treatment should be conducted on the same principle as in the oblique fracture of a single condyle, excepting that some degree of extension may be necessary to correct the overlapping of the fragments. If this tendency to shortening should be very great, permanent extension with the long splint may be employed, and when the inflammatory swelling has subsided, the broken condyles may be steadied and maintained in contact with each other by a circular bandage round the knee.

Fractures of this description when compound will, in the majority of cases, call for amputation. Sir A. Cooper, however, mentions the case of a boy under the care of Mr. Travers, in St. Thomas's Hospital, in which the external condyle, which protruded, was, after a time, removed, and the patient recovered so favorably that five months after the accident he had free use of the joint, and was able to walk without any support. (*On Dislocations, &c.* ed. by B. Cooper, p. 241.)]

FRACTURES OF THE PATELLA

May be produced either by external violence, or by the action of the extensor muscles. They may be either transverse or longitudinal in their direction.—When the patella is broken longitudinally the cause is always outward violence; but when the fracture is transverse, though it also may originate from a blow or fall on the part, it is in all common cases, the result of the violent action of the extensor muscles of the leg. In the latter case, which is by far the most common, the fall is subsequent to the fracture, and, as Camper has remarked, it is mostly only an effect of it. For instance, the line of gravity of the body is, by

some cause or another, inclined backward; the muscles in front contract to bring it forward again; the extensors act on the patella; this breaks, and the fall ensues. That it is the action of the muscles, and not the fall, which usually breaks the knee-pan, is well ascertained. Sometimes the fracture occurs, though the patient completely succeeds in preventing himself from falling backward, as we find exemplified in two cases reported by Sir A. Cooper. (*Surgical Essays*, part ii. p. 85.) A soldier broke the patella in endeavouring to kick his serjeant; the olecranon has been broken in throwing a stone. In the operating theatre of the Hôtel-Dieu, both the knee-pans of a patient were broken by the violent spasms of the muscles, which followed an operation for the stone. It is only of late years, however, that the true mode, in which the bone is usually broken, has been understood. For the production of a transverse fracture of the knee-pan, the extensor muscles of the leg need not act with a convulsive force, their ordinary action being strong enough to produce the effect in question, when the body is inclined backward, and the patient is in danger of falling upon his occiput. In this state, the thigh being bent, the extensor muscles of the leg contract powerfully, in order to bring the body forwards, and prevent the fall backwards; and the patella, whose posterior surface then rests only by a point against the fore part of the condyles of the femur, is placed between the resistance of the ligament binding it to the tibia, and the action of the extensor muscles. A fracture now happens the more easily, because, by the flexion of the knee, the line of the extensor muscles, and that of the ligament of the patella, are rendered oblique, with respect to the vertical axis of this bone, which is bent backwards at the point where it rests upon the condyles. (See *Boyer, Mal. Chir.* t. iii. p. 322; *C. Bell's Operative Surgery*, vol. ii. p. 201, 8vo. Lond. 1809; *A. Cooper's Surgical Essays*, part ii. p. 86.) By violent spasmodic action of the extensor muscles, however, the patella may be broken transversely, while the limb is perfectly straight. The force of the muscles occasionally ruptures the common tendon of the extensor muscles, or what is more frequent, the ligament of the patella. Of these cases, Petit, Desault, and Sabatier, met with examples. [Chelius mentions five cases in which rupture of this ligament took place. See *Transl. by South*, vol. i. p. 580.]

In transverse fractures, there is a considerable separation between the two fragments of the bone, very perceptible to the finger, when the hand is placed on the knee. This separation is not occasioned equally by both portions; the upper one, embraced by the extensor muscles, is drawn upward very forcibly by them, the patella no longer resisting, while the inferior portion, being merely connected with the ligament below, is not moved by any muscle, and can only be displaced by the motions of the leg, to which it is attached. Hence, the separation is least when the limb is extended, being then only produced by the upper fragment; greatest, when the limb is bent, because both pieces contribute to it; and it may be increased or diminished, by bending the knee more or less.

[M. Malgaigne has shown that the separation is not, after a time, occasioned solely by the ascent of the upper fragment, but that it depends partly upon the descent of the lower portion, in conse-

quence of the gradual contraction which the ligamentum patellæ undergoes. In one case he found this ligament shortened more than an inch, and it was not more than half the length of the ligament on the uninjured side. The retraction of the ligament had in this instance produced a greater effect even than the contraction of the muscles. But, besides being separated from each other, the fractured portions of bone undergo a displacement of another kind; they are tilted forwards, so that the anterior edges of the fractured surfaces are more widely separated than the posterior. This obliquity does not affect both pieces to the same extent, but is much more marked in the lower than in the upper. M. Malgaigne believes this is principally due to the slow contraction of the ligamentum patellæ, the anterior fibres of which, being longer than the others, undergo a greater amount of shortening, and draw downwards the anterior surface of the lower fragment to which they adhere. The movement is increased by any apparatus which aims at the approximation of the fragments by means of circular constriction above and below the patella. (See *Malgaigne, Traité des Fract.* t. i. p. 755.)]

As Boyer has particularly noticed, the laceration, or not, of the tendinous expansion, upon the front of the patella, makes a material difference in these cases, because it is a part of great importance in the cure. According to this author, a portion of it, in simple fractures of the patella, generally escapes laceration, and the separation of the fragments is then not very considerable; but the violent action of the extensor muscles, a fall subsequent to the fracture, or the bending of the knee too much, may separate the pieces of bone far from each other, and rupture the tendinous expansion. (*Mal. Chir.* t. iii. p. 328.) According to Sir A. Cooper, "when the ligament is but little torn, the separation will be but half an inch; but under great extent of injury, the bone may be drawn five inches upwards, the capsular ligament, and tendinous aponeurosis covering it, being then greatly lacerated." (*Surgical Essays*, part ii. p. 84.)

The upper portion of bone may be moved transversely, and pain is thus excited, but no crepitus can be felt, as the two pieces of bone are not sufficiently near each other. When the swelling of the knee, consequent on fractures of the patella, is great, the symptoms of the injury may be more or less obscure. However, in consequence of the inability of the extensor muscles to move the leg, except in a few cases where the fracture is very low, the patient cannot stand without difficulty, and is unable to walk.

The broken patella commonly unites by means of a ligamentous substance, instead of bone. However, that an osseous union may follow a transverse fracture of the patella, and still more frequently a perpendicular one, is a fact of which there is not now the slightest doubt. Thus, Lallement has published an unequivocal specimen of a transverse fracture united by bone, with the history of the case, and the appearances after the death of the patient from some other affection. (*Boyer, Mal. Chir.* t. iii. p. 355, &c.) In the collection of Dr. William Hunter, there is one well-marked instance of the bony union of a transverse fracture of the patella, and other examples have been seen in the dead subject by Mr. Wilson. (*On the Structure, Physiology, &c. of the Skeleton*,

p. 240.) In Sir Charles Bell's museum were likewise similar specimens, one or two of which are now in the museum of University College. (*On Injuries of the Spine and Thigh-bone*, pp. 57, 58.) The reason why transverse fractures of the patella do not commonly unite by callus, is not owing to the want of power in this bone to produce an osseous connecting substance; for, as Larrey has several times noticed, if the fragments are kept in perfect contact by means of a suitable apparatus, their bony reunion becomes so complete, that scarcely any vestige of the injury can afterwards be traced. (*Journ. Complém.* t. viii. p. 114.) And what must add strength to the purport of the foregoing remarks, is the consideration, that perpendicular or longitudinal fractures of the patella, which are not liable to any displacement from the action of the extensor muscles of the leg, readily admit of bony union. (*Wilson, On the Structure and Physiology, &c. of the Skeleton*, p. 239.) This is a statement which, I think, could not be rendered doubtful by any experiments made on animals, without the advantages of quietude and proper treatment. Yet there are other facts related, which prove that, both in longitudinal and transverse fractures, a ligamentous union is generally produced, when the fragments are separated; but, if these are not drawn asunder, an osseous union takes place. Thus, in one case, reported by Sir A. Cooper, one third of the patella was separated from the rest of this bone, and had united by ligament, a free motion being left between the fragments. (*Surgical Essays*, part ii. p. 94.) The same gentleman divided the patella longitudinally in a dog, without extending the division into the tendon above, or the ligament below, so that the fragments could not be separated. In three weeks, a close bony union was the result. (p. 95.) A case is also related, in which a gentleman fractured the patella transversely, and the lower portion likewise perpendicularly. The transverse fracture united as usual, by ligament; the perpendicular one, by bone. (p. 96.)

Pott and some others thought that an interspace between the two pieces of the patella, with a certain length of the connecting substance, might be advantageous in the motion of the joint; but Desault, Boyer, Sir A. Cooper, Sir J. Earle, and others, have always found that the greater the distance between the two pieces of the bone, the greater is the difficulty afterwards in walking up a rising or over an unequal ground.

[Much separation of the fragments must also, as Sir A. Cooper has remarked, produce weakness in the limb in consequence of the shortening of the extensor muscles, for the shortening will necessarily be attended with a proportionate diminution of their power. This weakness of action will also in process of time cause atrophy and degeneration in the muscular structure. (See *Malgaigne*, vol. i. p. 454.)]

According to the researches of Mr. W. Adams, it appears that it is only when the fragments are separated by a short interval that their fractured surfaces become firmly united by a new fibrous or ligamentous material; when the separation exceeds an inch or an inch and a half, the bond of union consists merely of a thickening of the aponeurotic structures which pass over the front of the patella, and not of any new plastic material that has been effused between the fragments.

A second fracture in the same patella, or rather—according to the observation of most surgeons—a rupture of the ligamentous union, is by no means a rare occurrence; it has been known to happen for the third and even for the fourth time in the same limb. The second injury, however, is not always rupture of the ligament, though probably this is most frequent; Mr. Erichsen states that in all the cases which he has seen, it has been a real fracture and not a rupture of the ligament—the second fracture having been always situated just above the line of the original one.

It has also been repeatedly noticed that persons who have broken one patella will, at some subsequent period, suffer from a similar injury on the opposite side. The weakness of the injured limb probably induces the patient to rely more for support on the sound limb, and especially so in any sudden emergency, till at last, during some effort more violent than usual, this in its turn snaps across.]

A very singular case is mentioned by Sir A. Cooper, where a patella, which had been formerly broken, and united by ligament, was again divided into two portions, in consequence of the destruction of the uniting medium by ulceration. (Vol. cit. p. 100.) A case is also on record where the ligamentous uniting substance was so incorporated with the skin that, when the latter happened to be lacerated, the knee-joint was laid open, and amputation became necessary. (*C. Bell, Op. Surgery*, vol. ii. p. 204.)

Treatment.—The chief indications are to overcome the action of the extensor muscles of the leg, and to keep the fragments as near each other as possible, partly by a judicious position of the limb, and partly by mechanical means. The first indication is fulfilled by relaxing the abovementioned muscles: 1st, by extending the leg; 2ndly, by bending the thigh on the pelvis, or, in other words, raising the femur so that the distance between the knee and anterior inferior spinous process of the ilium, and brim of the acetabulum, may be as little as possible; which object, however, will also require the body to be raised, and the pelvis somewhat inclined forwards, so that the rectus may be perfectly relaxed. In short, as Richter long ago advised, the patient should be almost in a sitting posture, the trunk forming a right angle with the thigh. (*Bibl. Chir.* b. vi. p. 611. Göttingen, 1782.) 3rdly, the muscles are to be compressed with a roller. The second indication, or that of placing and maintaining the fragments in contact, or as nearly so as circumstances will allow, is in a great measure already answered by the above-recommended position of the limb and trunk; but it is not perfectly fulfilled unless the upper portion of the bone be also pressed towards the lower fragment, and mechanically held in this situation by the pressure of an apparatus or bandage. And, in pushing the upper fragment towards the lower one, the surgeon should always be careful that the skin be not depressed and pinched between them.

After putting the patient to bed upon a mattress, and in the desirable posture, with the limb confined, supported, and raised, as above directed, upon a well-padded hollow splint, Sir A. Cooper applies at first no bandage to the knee, but covers it with linen wet with a lotion, composed of liq. plumbi acet. dilut. $\frac{3}{4}$ v. and spir. vin. $\frac{3}{4}$ j. If, on

the succeeding day or two, there be much tension, or ecchymosis, leeches should be applied, and the lotion continued; but the employment of a bandage is not to commence until the tension has subsided; for Sir A. Cooper assures us that he has seen the greatest suffering, and such swelling as threatened gangrene, produced in these cases by the too early use of a roller. Instead of a circular bandage, placed above and below the broken bone, and drawn together with tape, &c. so as to bring the upper fragment towards the lower one, this experienced surgeon prefers the following method:—A leathern strap is buckled round the thigh, above the broken and elevated portion of bone, and from this circular piece of leather, another strap passes under the middle of the foot, the leg being extended and the foot considerably raised. This strap is brought up to each side of the patella, and buckled to the leathern band already applied to the lower part of the thigh. It may also be fastened to the foot, or any part of the leg, with tapes. The limb is to be confined in this position five weeks if the patient be an adult, and six if advanced in years. Then a slight passive motion is to be begun, and to be gently increased, from day to day, until the flexion of the knee is complete. (*Surgical Essays*, part ii. p. 91.) But, although the impropriety of making any constriction of the knee with a bandage, while the skin is swelled and inflamed, must be obvious, the surgeon ought to be apprised that such swelling and inflammation ought not to occasion the least delay in placing the limb in the right posture, and pressing the upper fragment towards the lower one. Mohrenheim ascribes the lameness formerly so frequent after this fracture, partly to the custom of not thinking of bringing the pieces of bone together until the swelling had subsided, and partly to the fashion of bending the joint too soon, with the view of preserving its motion. But, says he, nothing can be clearer than that it is most advantageous to attend to the union of the fracture first, and to the flexibility of the joint afterwards. (*Beobachtungen*, b. ii. 8vo. 1783.) Boyer has likewise remarked that the uniting substance is apt to yield and become lengthened by bending the knee too early, and he therefore never allows this motion to be performed before the end of two months. When the ligamentous substance is long, and the patient very slow in regaining the use of the extensor muscles, he should sit every day on a table and endeavour to bring them into action; and as this increases, a weight may be affixed to the foot, as Hunter, Sheldon, &c. recommend.

Nothing keeps the leg more surely extended than a long, broad, excavated splint, with a suitable pad applied to the posterior part of the thigh and leg, and fixed there with a roller, while the thigh itself is to be bent by raising the whole limb from the heel to the top of the thigh, with pillows, which, of course, must form a gradual ascent from the tuberosity of the ischium to the foot.

[M. Malgaigne objects to the various methods which have been recommended for the purpose of approximating the fragments, and which act by circular compression of the limb, not only on account of their inefficiency, but because they depress the tendon of the extensor muscles on the one side, and the ligamentum patellæ on the other, in such a manner as to tilt the fragments forward, and to separate the fractured surfaces in front.

Contact may, indeed, be obtained; but it is limited to the posterior border of the fracture, while there remains a wide interval in front. He has, therefore, devised an instrument to act upon the pieces of bone themselves, without taking its bearings upon either the integument or tendons. The instrument terminates above and below in two curved sharp-pointed hooks, which he passes through the skin and firmly implants in the upper and lower borders of the bone. The apparatus is so contrived as to admit of its ends being approximated by means of a screw; and in this way the fragments can be drawn together. Osseous union was thus obtained in two cases which he relates, and in another the separation was not more than a quarter of an inch. A firm hold was readily obtained by the lower hooks, which were inserted beneath the thin lower border of the bone, so as to embrace it in their concavity; but there was more difficulty with the upper ones, which, being inserted upon the sloping upper surface of the patella, were found to have a tendency after a time to slip downwards. It was necessary to insert these very deeply, or they only took hold of the tendinous structures on the front of the bone, and they required to be held very firmly in their place until the screw was tightened. The apparatus was retained from three to four weeks, and in one instance as long as forty-one days. The irritation produced was very trifling, and the punctures healed in two or three days after the hooks were removed. (See *Traité des Fract.* t. i. p. 771.)]

In the treatment of a *longitudinal* or *perpendicular* fracture of the patella, the leg should be kept extended, leeches used, and a cold lotion applied. After a few days a roller is to be put round the limb, and then a laced knee-cap, with straps buckled round the limb above and below the patella, and a pad on each side to bring its parts as nearly as possible into contact. (Sir A. Cooper, vol. cit. p. 96.) The experience of Dupuytren confirms the fact that a longitudinal fracture of the patella is soon firmly consolidated. (*Annuaire Méd. Chir. de Paris*, p. 94. 4to. Paris, 1819.)

[Dupuytren thought that the action of the muscles had no tendency to displace the fragments in a longitudinal fracture. Sir A. Cooper even believed that it would approximate them. M. Malgaigne has, however, well explained that these views were erroneous; and that on the one hand the fibres of the vastus externus which pass obliquely forwards to be inserted into the external angle of the patella, and on the other those of the vastus internus, which are attached along the whole length of the internal border of the bone, must necessarily tend to draw the fragments apart. The separation is greater when the knee is flexed, because this position puts the extensor muscles on the stretch, but it is still present when the knee is extended, unless the preservation of the fibrous tissues should obviate the effect of the muscular contraction. The interval is greater at the upper than at the lower end of the bone. The knee should be kept in the extended position; but there is no necessity to flex the thigh upon the pelvis, since the rectus muscle has no influence in causing the separation. Compresses should be carefully fixed on each side of the bone, to insure the contact of the fractured surfaces.]

Compound fractures of the patella frequently terminate in the death of the patient, unless ampu-

tation be performed early. The injury, however, does not invariably lead either to the loss of life or limb. I saw a case in St. Bartholomew's Hospital, in the year 1820, under Mr. Vincent, where the patella was broken to pieces, and the opening so extensive that the fingers readily passed into the joint; yet, after a tedious confinement, the formation of abscesses, and the separation of several fragments of bone, the patient recovered with a stiff joint. In general, however, I believe, with Sir A. Cooper, that in compound fractures of the patella, if the laceration be extensive, or the contusion very considerable, amputation will be required; but, if the wound be small, the patient not irritable, and no sloughing of the integuments, or ligament, likely to occur, it will be best to try to save the limb. (Vol. cit. p. 99.) The wound should be re-united as speedily as possible, and advantage taken of evaporating lotions, perfect rest in a desirable posture, a very low regimen, leeches, venesection, and saline opening medicines. Since the above remarks were first drawn up, I saw another case of bad compound fracture of the patella in St. Bartholomew's Hospital, where it had been about a month. No fragments of bone had then been removed, but a good deal of matter issued daily from the wound, and the patient was in considerable danger of losing his limb, or even his life.

FRACTURES OF THE LEG.

[Fractures of the leg are among the most frequent of all fractures. In 1101 cases of fracture occurring at the Middlesex Hospital, and recorded by Mr. Lonsdale, 289 were fractures of the leg; in 226 fractures occurring at Guy's Hospital, and recorded by Dr. Wilkinson King, 66 were of the leg; and in 946 fractures occurring at the Pennsylvania Hospital, and recorded by Dr. G. W. Norris, 293 were of the leg. (*Pirrie's Surgery*, p. 201.) Thus, in a total of 2267 cases of fracture, 638, or nearly 1 in $3\frac{1}{2}$, were fractures of the leg. This proportion corresponds almost exactly with the statistics collected by M. Malgaigne from the records of the Hôtel-Dieu, for in a total of 2328 fractures he found 652 were of the leg, being as nearly as possible in the same proportion.]

Fractures of the leg, like those of the fore-arm, may be divided into three classes, viz.:—1. Fractures of both bones. 2. Fractures of the tibia. 3. Fractures of the fibula. Of these varieties the first is by far the most frequent: in Mr. Lonsdale's table, of 289 fractures of the leg, 197 were of both bones, 41 of the tibia singly, and 51 of the fibula; and in that of M. Malgaigne, out of 652, 515 were of both bones, 29 only of the tibia, and 108 of the fibula.]

In a review of the position and strength of the two bones of the leg, it will appear that the tibia supports alone the whole weight of the body, as well as every shock directed in the axis of the limb, and many kinds of force applied also in the transverse direction, without operating upon any particular point. Hence the frequency of fractures of the tibia; and, if the fibula is generally broken likewise, the latter injury is subsequent to the other, and takes place because this slender bone is not capable of bearing the weight of the body, the impulse of external violence, or even the action of the muscles, after the tibia has given

way. (*Dupuytren, Annuaire Méd. Chir. des Hôpitaux de Paris*, p. 15. 4to. Paris, 1819.) On the other hand, as the same distinguished surgeon remarks, the fibula being principally designed as a support for the outside of the foot, it is particularly when this function is to be executed and its lower end has to make resistance to efforts made in that direction, that it is fractured; and, if the lower part of the tibia be also sometimes broken by the same force, it is almost always consecutively, and not by the effect of a direct and simultaneous action upon the two bones. (p. 17.) The fibula may, however, like the tibia, be broken by direct violence.

Fractures of both Bones of the Leg.

[Fractures of both bones may be caused either by direct or indirect violence. In the former case, as, for instance, when the wheel of a carriage passes over the limb, when it is kicked by a horse, or when a heavy substance such as a paving-stone falls against it, both bones are usually broken at the same level, and the fracture takes place at that part of the limb to which the force is applied; but in the fracture from indirect violence, as when a person falls from a height and the sole of the foot is the first part to reach the ground, the tibia usually gives way in its lower third, which is its weakest part, and the fibula, being unable to sustain the weight of the body thus suddenly thrown upon it, gives way consecutively, not always or necessarily at the same level, but in most cases several inches higher up. Sometimes, as M. Nélaton has remarked, one bone is broken by direct and the other by indirect violence, as when the tibia is fractured by a blow, and the fibula is broken secondarily, on account of its not being able by itself to support the weight of the body. This is especially likely to happen if, after the fracture of the tibia, the patient makes an effort to walk, or struggles to prevent himself from falling.]

The usual symptoms denoting a fracture of both bones of the leg, are a change in the direction and shape of the limb, pain, and incapability of walking, or bearing upon the limb, mobility of the fractured pieces, and a distinct crepitus.

The fracture may be transverse or oblique. The first case is most common in children, and in adults, who meet with fracture of the tibia above the lower fourth of the bone. (See *Sanson, in Dict. de Méd. et de Chir. Pratiques*, t. viii. p. 557.)

In transverse fractures a longitudinal displacement cannot easily take place, on account of the considerable extent of the surfaces of bone; but, in oblique fractures, the inferior fragments are almost always drawn upwards by the action of the posterior muscles of the leg.

The direction of the obliquity is in the majority of cases from above downwards, and from without inwards, the end of the upper fragment mostly projecting and presenting itself under the skin at the front and inner part of the leg. Sometimes, however, when the solution of continuity is obliquely downward and outward, the anterior projection will be produced by the lower piece. In both kinds of displacement, the pointed ends of the bones may tear and penetrate the integuments, and cause a compound fracture.

An angular displacement may be produced either by the action of the posterior muscles of the leg, or the weight of the foot, and, in both cases,

the angle projects forwards. But it may be directed posteriorly if the heel be too much raised. A rotatory displacement, most commonly happening in the direction outwards, is produced by the inclination of the foot; but, if this be turned too much inwards, the rotatory displacement will be in that direction.

Fractures near the knee are not very subject to displacement, on account of the thickness of the tibia at that part. When displacement does occur, the upper piece is usually tilted forwards, under the influence of the extensor muscles of the knee-joint. Fractures near the knee are more dangerous than those of the middle of the bone, because often followed by inflammation of the knee-joint. Fractures close to the ankle are also severe accidents. Oblique fractures are more difficult of management than transverse, and, when the displacement is considerable, the integuments are in danger of being torn by the projecting points of the superior portion of the tibia.

To bad compound fractures of the leg most of the observations already delivered on compound fractures in general, are applicable.

Treatment of Fractures of both Bones of the Leg.—As in cases of fractured thighs, the practitioner may adopt either a bent or a straight position of the limb: in this country, surgeons mostly follow Pott's advice, and select the first one. A few, however, are advocates for the extended position, and amongst them Dr. Houston deserves to be particularly noticed, on account of the ingenuity of his arguments, the novelty of his views respecting the causes of spasmodic action of the muscles in these cases, and the facts which he brings forward. (See *Dublin Journ. of Med. Science*, vol. viii.) But, notwithstanding his objections to the bent position, experience has taught me that it is, generally speaking, the most advantageous for a broken leg. The strong muscles of the calf are the powers which tend to displace the ends of the fracture, and their relaxation is a thing of the first importance. It is quite different in the thigh, where the muscles are so numerous that the attempt to relax, by any position of the limb, all such as have the power of displacing the fragments, would be in vain. I am ready to acknowledge, however, that, in Pott's method, the apparatus is defective, inasmuch as it does not keep the knee-joint from moving; yet it is certain that such motion has not so injurious an effect upon fractures of the leg as it has upon those of the thigh. When the case is complicated with a wound, which cannot be dressed in the bent posture of the limb without great disturbance of the fracture, the straight position ought unquestionably to be preferred. With respect to one of Pott's objections to this position, viz. that it makes the knee stiff for a long while afterwards, I suspect that we should not lay much stress upon the circumstance, because, as Boyer has correctly observed, it is always the joint situated below the fracture that is thus affected.

In the fracture of both tibia and fibula (says Pott) the patient should lie on the injured side with his knee moderately bent; the thigh, body, and leg being in the same position as in the broken thigh. If common splints be used, one should be placed underneath the leg, extending from above the knee to below the ankle, the foot being properly supported by pillows, bolsters, &c.; and another splint

of the same length should be placed on the upper side, comprehending both joints in the same manner.

The strong muscles of the leg being relaxed, the surgeon is to make such extension as seems requisite for bringing the ends of the fracture into even apposition. Then he is carefully to raise the leg a little way from the surface of the bed by taking firm hold of the limb above and below the fracture, and elevating the broken bones together, in such a way as shall keep both the upper and lower portions as nearly as possible on the same level. At this moment an assistant should put exactly beneath the leg the under splint, which has been previously made ready by covering it with a soft pad, and laying over this an eighteen-tailed bandage. The limb is now to be gently depressed till it rests on the apparatus. The surgeon, before proceeding further, must once more observe that the ends of the bones are evenly in contact. Being assured of this important point, he is to apply a piece of soap-plaster, and lay down the tails of the bandage. Another soft pad, well filled with tow, is next to be put over the upper surface of the leg, and over that the other splint, and then the straps are to be fastened.

This mode of treatment, as preferred by Pott and his followers, is seldom adopted at the present time. The disadvantage of leaving the limb, and especially the knee, movable, must be self-evident; and whoever has had the opportunity of observing the treatment of fractures of the leg in a slightly flexed position, on M^rIntyre's double inclined plane, with the patient on his back, must be fully convinced of its superiority and greater simplicity. No eighteen-tailed bandage is required. The whole limb, including knee and foot, is kept perfectly steady. A circular hole, as advised by Mr. Liston, is made in the apparatus under the heel, so as to lessen the pressure in that situation, and the chance of ulceration, or sloughing. The apparatus, lined by proper pads, receives the limb; the foot is supported upon the foot-piece, with the intervention of soft materials; and the limb, from the lower part of the thigh down to the toes, is then encircled, together with the double inclined plane and its foot-piece, with common rollers. Of these we generally employ three: one for the thigh, knee, and upper part of the leg; a second for the foot and the leg; and a third for the central part of the leg, and place of the fracture, which is put on last. One great advantage of this method is, that the central piece of the roller may be removed as often as the surgeon pleases, and the fracture examined, or if a compound one the wound cleaned and dressed, without the slightest disturbance of the fracture itself, or any motion of the limb.

[It is an advantage to have the foot-piece fixed in such a manner as to admit of lateral movements, so that the toes may be directed outwards or inwards, by which means any tendency to displacement of the foot in either of these directions may be effectually counteracted.

Side splints, with foot-pieces, are often employed for the treatment of fractures of the leg, and in ordinary cases they answer sufficiently well; but they do not afford the same steadiness and security against displacement, especially in the antero-posterior direction, as the apparatus last described, nor are they so comfortable to the patient.

Another excellent mode of treating fractures of

the leg is by the swing apparatus introduced by Mr. Luke, and in common use at the London Hospital. The fracture is first properly adjusted and placed in a kind of fracture box, well furnished with cushions; and the whole is then placed in the interior of an arched cradle, from the upper bar of which it is suspended by straps. A modification of Mr. Luke's apparatus, with some additions, has been devised by Mr. James Salter, of King's College, and a drawing of it is given by Mr. Fergusson. (See *Pract. Surg.* ed. 3. p. 404.) By this method of swinging the limb the fracture is less likely to be disturbed by slight movements of the patient than when the apparatus rests immovably upon his bed. After the lapse of a fortnight or three weeks, if the case progresses favourably, the starched bandage, strengthened with pasteboard, may be substituted for these more cumbrous appliances, and the patient may be allowed to walk about on crutches, with his foot supported by a strap which is buckled over his shoulders. Many continental surgeons and some in this country recommend the starched bandage from the first, and allow the patient to move about a day or two after the accident. The more common practice in England is, however, to use it more as an auxiliary to the other methods, and after the lapse of time above mentioned. (See *ante*, p. 688.)

In some cases it becomes necessary to employ a certain amount of permanent extension to prevent the tendency to retraction and overlapping of the fragments, and for this purpose Desault's long splint or some modification of it may be employed. Mr. Fergusson has contrived a very convenient and simple splint suitable for cases of this kind, and also for fractures of the thigh. It consists of a light iron bar to represent the long splint, with a movable foot-piece attached by which the toes can be pointed in either direction, while the whole is supported upon the bed by a sort of cross bar attached to its lower end. By having the apparatus thus supported and steadied, the troublesome tendency so often noticed with the long splint of the foot to turn out, or of the splint to turn forwards, is prevented. For a drawing and description of this splint, see *Fergusson, Pract. Surg.* ed. 3. p. 401.

In some cases of oblique fracture, the upper fragment has a strong tendency to project forwards under the influence, as is usually believed, of the extensors of the knee-joint, and obstinately resists all efforts to keep it in its place either by position or pressure. For cases of this kind, M. Maligne has devised an ingenious plan of treatment, by which *direct pressure* is made upon the displaced portion of bone itself. The limb is placed on a double inclined plane, well padded, with the foot supported against a foot-piece. His apparatus consists of an arched plate of iron, intended to surround the anterior three-fourths of the leg, at about a finger's-breadth distance from it; at each end of this plate is an aperture through which a strap and buckle may be passed, by means of which the plate can be fixed firmly to the inclined plane a little distance above the seat of the fracture. There is an aperture in the centre of the arched iron plate, grooved for a screw; the screw which passes through this opening ends in a sharp point, which is intended to be inserted through the skin into the projecting portion of bone.

This having been done, by a few turns of the screw the bone is effectually pressed down into its place. If the patient remains quiet, the point may be maintained in its place for twenty or thirty days without producing suppuration or inflammation, or even redness, and if it has not slipped in consequence of having been inserted too obliquely upon the internal surface of the tibia, the small wound which it leaves will very rapidly cicatrise. M. Malgaigne states that in the majority of cases in which this instrument was employed, not the slightest projection remained on the surface of the bone. (*Traité des Fract.* t. i. p. 795.)

FRACTURES OF THE TIBIA.

Fracture of the tibia alone is much less frequent than fracture of both bones; indeed, when the size of the tibia is compared with that of the fibula, and the close connection of these bones to each other is remembered, an opinion might be formed that the first could never be broken without the second. Experience, however, proves the contrary; and reasons for this fact may be deduced from the consideration, that the tibia is the bone which supports the weight of the body, and that it is situated at the fore part of the limb, simply covered by the skin, and much exposed to the effects of direct violence. (See *Boyer, Mal. Chir.* t. iii. p. 373.)

Fractures at any point of the two upper thirds of the tibia can scarcely happen, except from direct violence, as that from a gunshot wound, a blow, or the passage of a heavy body over the leg. But the lower fourth is exposed both to the action of direct causes, and to fractures by *contre-coup*, as they are termed, like those which happen from a fall on the sole of the foot from a considerable height. Fractures of the lower end of the tibia alone are not common; the fibula being almost always broken at the same time. (*Sanson, Dict. de Med. et de Chir. Pratiques*, t. viii. p. 557.) When the tibia alone is broken, the fracture is frequently transverse. When the injury happens near the knee, the great extent of the fractured surfaces prevents any considerable displacement of the fragments; and the fibula, acting as a support on the external side, contributes also to this effect. Boyer, however, saw one instance in which the tibia had been broken by the kick of a horse, and the fragments displaced in the direction of the axis of the bone, which displacement could not be rectified, and the bone remained permanently arched.

[Sometimes there may be a fracture of the upper extremity of the tibia above the tibio-fibular articulation. Sir A. Cooper speaks of an oblique fracture of the upper extremity of the tibia, sometimes extending into the knee-joint and sometimes not. When the fracture is just below the joint, but not extending into it, the lower portion has a tendency to be drawn upwards on one side or other of the knee-joint, according as the obliquity takes a direction inwards or outwards. (See *Sir A. Cooper, On Dislocations, &c. B. Cooper's ed.* p. 250.) When there is an oblique fracture of the upper end of the tibia into the knee-joint, the smaller detached fragment is usually not much displaced, but it may be felt to be movable upon the rest of the bone, and by moving it crepitus may be readily obtained. As in the fracture of the condyles of

the femur into the joint, great swelling and inflammation of the knee rapidly supervene, and permanent stiffness is very likely to result.]

The absence of displacement sometimes obscures the diagnosis of fractures of the tibia, and the difficulty is further increased by the little pain and inconvenience occasionally attending such a fracture, with which the patient has been known even to walk.

Whenever there is reason to suspect the accident in consequence of a blow or a fall on the leg, the part should be minutely examined. The fingers are to be moved along the anterior surface and sharp edge of the tibia, the slightest inequality in which may be easily perceived, on account of their being covered only by the skin; and the motion of the pieces may be distinguished, by grasping the opposite ends of the bone, and pushing them in contrary directions. However, this motion, and the crepitus, are not always very plain, on account of the fibula not allowing the fractured portions to be sufficiently moved on one another.

Treatment.—[The treatment of a fracture of the tibia alone should be conducted in the same manner as a fracture of both bones; but there is usually not much tendency to displacement, and the case is therefore more easily manageable. Lateral splints may be used, or Liston's modification of M'Intyre's apparatus; the latter will probably be found more comfortable to the patient. After a few days, when the inflammation has subsided, the starch bandage may be substituted for the splints, and the patient may be allowed to move about on crutches.]

In an oblique fracture of the head of the tibia, extending into the knee-joint, Sir A. Cooper recommends the straight position, because the femur preserves the proper adaptation of the fractured tibia by serving as a splint to its upper portion, and keeping the articular surfaces in apposition. [Probably a slightly flexed position would answer equally well, and be less likely to be followed by permanent stiffness of the joint.] A roller is to be used for pressing one fragment towards the other; a pasteboard splint is also to be applied with the same view; and early passive motion of the joint is to be practised, in order to prevent ankylosis. When the fracture is oblique, but does not reach into the joint, he prefers placing the limb on the double inclined plane, for, the cause of the deformity being the elevation of the lower portion of the tibia, the weight of the leg keeps the limb constantly extended as it hangs over the angle of the inclined plane, and thus the bone is brought into as accurate apposition as the nature of the fracture permits. (*On Dislocations, &c. B. Cooper's ed.* p. 250.)

FRACTURES OF THE FIBULA.

Fractures of the fibula are divided by Dupuytren, Boyer, and all the best writers on this subject, into two kinds: first, those in which the force is applied directly to the bone itself; secondly, the more frequent and important cases, in which the force operates upon the fibula, through the medium of the foot. In the first kind the fracture may happen at any part of the bone; in the second variety it is very rarely more than three inches above the extremity of the malleolus externus. Dupuytren states that of 207 fractures of

the fibula observed by him, seven-tenths of them happened to the right leg; only one-tenth were caused by direct violence, such as a blow or the passage of some heavy body over the limb; the remaining nine-tenths were produced by indirect force applied to the foot either in the direction of adduction or abduction, six-tenths being caused by violent adductive motions of the foot, three-tenths by similar abductive movements. With respect to the seat of the fracture of the fibula, in five-tenths it was two inches from the lowermost point of the external malleolus; in three-tenths, below this point; and in two above it. Cases, within two inches of the external malleolus, were often complicated with displacement of the foot; the others but rarely. (See *Dupuytren*, in *Annuaire Méd. Chir. des Hôpitaux de Paris*, 4to. Paris, 1819; also, in *Leçons Orales de Clin. Chir.* t. i. art. 10, p. 189.)

With respect to the first class of cases, *i. e.* those arising from *direct* causes, the situation of the fibula on the outer side of the leg, a situation which would seem to expose it much to external violence; its slenderness; the interspace left between it and the tibia, at the middle part of the leg; and the way in which each end of it rests upon the latter bone, would lead one to expect that its middle portion must often be broken; yet the case is less frequent than might be apprehended. And, as *Dupuytren* observes, there are two reasons for this fact; *viz.* the protection which the fibula receives from the *peronæi* muscles, and the rarity of circumstances capable of producing a fracture by a direct cause. These fractures, which are not usually attended with deformity, and, in some cases, even do not hinder the patient from bearing upon the foot, cannot for the most part be ascertained, unless attention be paid to the manner in which the accident was produced, and to the presence of ecchymosis, and of more or less pain in the part which has been struck or pressed upon; together with a degree of irregularity of the fibula, perceptible by the fingers, and a more or less distinct mobility and crepitus of the ends of the fracture.

The usual causes of this sort of fracture are blows on the fibula, gunshot wounds, the fall of heavy bodies on the outside of the leg, or the passage of them over the same part. The foot may be slightly twisted, either inwards or outwards, but in most instances the accident is not accompanied by any of the symptoms so often complicating other fractures of the fibula, produced by distortion of the foot, and is easily cured by means of rest. A striking analogy may be remarked between fractures of the central part of the fibula, and those of the corresponding portion of the ulna, and this in respect to causes, symptoms, treatment, and consequences. Fractures of the middle of the ulna, like those of the body of the fibula, are always occasioned by blows or falls on the fractured part, or by violence applied directly to the bone. Such fractures are scarcely ever attended with any deformity in the limb, incapacity of moving it, or displacement of the fragments; and just as some individuals are able to walk with a broken fibula, others, notwithstanding a fracture of the ulna, are found capable of using their fore-arm nearly as well as if it were free from injury. The latter case, like that of a fracture of the fibula, can only be known by the recollection of the way in which the hurt was re-

ceived, the pain, ecchymosis, irregularities, motion, and crepitus, which last effects are also not very obvious so high up the bone. Like fractures of the body of the fibula, those of the body of the ulna only require rest and discutient applications, and very seldom the bandages, &c. necessary in the treatment of fractures of both bones of the forearm, or of the radius alone. (Vol. cit. p. 50.)

Fractures of the fibula from an *indirect* cause may happen from the foot being violently twisted either inwards or outwards. In both instances, the cause of the fracture is a change in the direction of the line in which the weight of the body is transmitted. In the first case, the said line, instead of following, as it commonly does, the axis of the tibia and falling upon the astragalus, crosses the lower end of the tibia and the ankle-joint obliquely from within outwards, and, after passing across the malleolus externus, extends to the outside of the member. The parts then supporting the weight of the body are the malleolus externus, and the lower end of the tibia; besides which state of parts, the same malleolus is subjected to the traction of the external lateral ligaments, which operate with great force, in consequence of those ligaments being now nearly at a right angle with the lower end of the fibula. The ligaments pull upon the lower border of the malleolus, while its upper part is pressed upon by the astragalus, which is propelled from within outwards by the tibia. The result is a fracture of the fibula an inch or an inch and a half above the extremity of the malleolus, and nearly opposite the lower edge of the tibia. The latter bone, being thicker and stronger than the fibula, generally resists, and, if the malleolus internus sometimes happens to break, it is secondarily, as an effect of the displacement of the foot inwards.

In the other example, where the foot is twisted outwards, the centre of gravity of the body, instead of following its usual course, obliquely crosses the lower end of the fibula, the ankle-joint, and the malleolus internus, and falls on the ground at a greater or lesser distance from the inner edge of the foot. On the one side, the internal lateral ligaments and malleolus, and on the other the lower end of the fibula, are then the parts which have to bear the weight of the whole body, and the force of the muscles; and they are also the parts which are torn and fractured,—first, the internal lateral ligaments, or the malleolus; and, secondly, the lower portion of the fibula. (*Annuaire Méd. Chir. de Paris*, 1819, pp. 66, 67.) Some of the symptoms of a fracture of the fibula, from an *indirect* cause, depend upon the fracture of that bone, and others upon the dislocation of the foot. They are divided by *Dupuytren* into two kinds; *viz.* *presumptive*, and *characteristic*. The first are, the way in which the patient received his hurt; a noise or sort of crack heard by him at the instant of the injury; a fixed pain at the lower part of the fibula; a difficulty or inability of walking; more or less swelling round the ankle, especially about the malleolus externus and lower portion of the fibula. The *characteristic symptoms* are, an irregularity and unnatural mobility of some point of the lower end of the fibula; a crepitus, which can be more or less distinctly felt by pressing upon and moving the part; mobility of the whole foot transversely, or horizontally; a facility of bringing the lower end of the fibula

towards the tibia by pressure; a change in the point of incidence of the axis of the limb upon the foot; distortion of the foot outwards, and sometimes backwards; rotation of the same part upon its axis from within outwards; an angular depression, more or less manifest, at the outer and lower part of the leg; projection of the internal malleolus; disappearance of almost all these symptoms, as soon as reduction is effected by a force applied to the foot; and their immediate recurrence when such force is discontinued, particularly if the limb be in the extended posture. (Vol. cit. p. 68.)

[The different modes in which the indirect fracture of the fibula may be produced have been the subject of much discussion. Dupuytren stated that in his 207 cases of fracture of the fibula (after setting apart one-tenth produced by direct violence), six-tenths arose from violent adductive movements of the foot, and three-tenths from similar abductive movements. This is not the opinion of surgeons generally in this country, who believe that the fracture from eversion is more frequent than that from inversion of the foot. Certainly the displacement of the foot which often accompanies or follows fracture of the fibula is much more frequent in the direction *outwards*, as described by Mr. Pott, than in the direction *inwards*, and it is impossible to understand how the foot can be displaced *outwards*, by violence which operates in such a direction as to *invert* it. Neither are we disposed to agree with Dupuytren, that the fracture of the fibula from *eversion* of the foot is always preceded by rupture of the internal lateral ligament or fracture of the internal malleolus; on the contrary, it is found that in many cases of simple fracture a little above the ankle attributed to eversion, and attended with little or no displacement of the foot, the symptoms are confined to the region of the fibula, and there is no evidence of injury in the neighbourhood of the internal lateral ligament or internal malleolus, which would necessarily be the case if the injury to these parts always preceded the fracture of the fibula. It is more reasonable to suppose that the twist of the foot first occasions the fracture of the fibula, and often stops short at this point; but if it continues to operate, or if, after the fracture, the patient should bear his weight on the injured limb, which has then lost its accustomed support on the outer side, the internal lateral ligament, or the internal malleolus, may give way, and the dislocation of the tibia inwards (or of the foot outwards) may be produced.

But although fracture of the fibula from eversion of the foot is probably the most frequent, there is little doubt that a twist of the foot *inwards* may also fracture the bone near its lower extremity. Dupuytren speaks of the fracture from inversion as often producing the same displacement of the foot which has just been described. It is difficult, however, to understand how this could occur. The explanation of such cases given by M. Malgaigne is more satisfactory: he believes that the inversion has first caused the fracture of the fibula, and that, the patients having attempted to bear their weight upon the injured limb, the dislocation of the foot outwards has been subsequently produced.

It is as well to remark that the words *outwards* and *inwards*, applied to these displacements of the

foot, are here used in their most obvious sense, and not in the sense in which Dupuytren employed them; what is here spoken of as displacement *inwards*, he was in the habit of describing as displacement *outwards*. (On this point, see *Dislocations of the Ankle-joint*, ante, p. 571.)

M. Maisonneuve rejects the fracture by abduction. According to him it is not abduction, but a rotation of the point of the foot outwards, which, in the majority of cases, is the cause of the fracture.

M. Malgaigne says that, judging from the statements of patients, the majority of fractures of the fibula take place from a movement of forced adduction of the foot, that is to say, from the effect of a fall or of a false step, in which the weight of the body falls upon the external border of the foot. He thinks it difficult to explain the mechanism of the accident, but remarks that the movement of adduction is usually accompanied by an inclination of the point of the foot inwards. Others are attributed by the patients to a fall or a false step in which the weight of the body falls upon the internal border of the foot, which is consequently carried in the direction of abduction; but he thinks that the abduction is almost necessarily associated with the rotation of the point of the foot outwards, as explained by M. Maisonneuve. His experience is that, whatever may be the cause of the fracture, its seat is usually from two and a half to three inches above the point of the malleolus, and rarely higher or lower than this.—*Traité des Fract.*, t. i. p. 808.]

In considering the varieties of simple fracture of the fibula with reference to the part of the bone fractured, the *first* to which Dupuytren adverts is that in which the bone is broken *more than three inches above the extremity of the malleolus externus; a case neither accompanied nor followed by any displacement of the foot*, and almost always produced by the direct application of violence to the broken part of the bone. The *second* variety is when the bone has been broken, either by direct or indirect force, *within three inches from the end of the malleolus externus, and when the foot is not displaced, though much displacement is possible*, and indeed often arises from the slightest effort or movement made by the patient after the injury. The most frequent point of fracture is about two inches and a half above the extremity of the outer malleolus. This is generally the place of a fracture caused by a twist of the foot outwards; but the accident may happen lower down, as is commonly seen when the fracture is occasioned by a twist of the foot inwards.

[It is doubtful whether the opinion of Dupuytren, which has been acquiesced in by most subsequent writers, that the fracture from inversion is situated nearer the malleolus than that from eversion, is really correct. As has been already mentioned, M. Malgaigne's opinion is, that whichever be the direction of the foot at the time of the injury, the fracture is in the great majority of cases situated from two and a half to three inches above the malleolus.]

These fractures of the fibula, abstractedly viewed, are not of much importance in themselves; but with reference to the manner in which they facilitate the dislocation of the foot, they are very serious.

Amongst the most frequent complications of fractures of the fibula, are the rupture of the in-

ternal lateral ligament, the detachment of the point of the inner malleolus, and fracture of the lower part of the tibia.

[These conditions, accompanied by dislocation of the foot outwards, constitute the injury known as Pott's fracture, or Pott's dislocation.]

Besides distortion of the foot outwards or inwards, as attending certain fractures of the fibula, another complication may be dislocation of the foot backwards, produced by the action of the muscles of the calf, and not by the same causes which broke the bone. However, whenever the malleolus internus has not given way, the dislocation is incomplete, and the foot is inclined outwards as well as backwards. (See *Dislocations of the Ankle-joint*.)

Although fractures of the middle and upper parts of the fibula are often overlooked and neglected, there is no displacement, and no ill consequences ensue; but things are different with regard to fractures of the lower end of the bone. In an example of fracture of the lower end of the fibula, that was mistaken for a sprain, the patient was permitted to walk about before union had taken place. The consequences were a distortion of the foot, and a tendency to a dislocation of it inwards, followed by such severe symptoms as nearly led to amputation. After a confinement of eight months, the limb was saved; but the ankle continued stiff, and of course the patient was yet a cripple. (See *J. Cloquet, Pathologie Chir.* p. 45.) Some interesting particulars of the dissection of a case of dislocation of the ankle, and fracture of the fibula, which had been neglected for three or four weeks, the limb being in continued exertion all this time, were published by Mr. Lawrence. (See *Med.-Chir. Trans.* vol. xvii. p. 58.)

[According to M. Malgaigne, an easy and sure means to distinguish between a sprain and a fracture of the fibula unattended with displacement, is to make pressure successively upon the lateral ligaments and upon the outer side of the fibula, from one to three inches above the malleolus: pain produced by pressure upon the ligaments indicates a sprain; pain confined to a limited portion of the fibula belongs almost exclusively to a dislocation. (t. i. p. 812.)]

Treatment of Fractures of the Fibula.—Pott's method of treating fractures of the fibula, complicated with luxation of the tibia, is described in the article DISLOCATIONS. I consider it a very inferior plan to that followed in University College Hospital with M'Intyre's apparatus. I would make the same observation with respect to Dupuytren's mode, ingenious and scientific as it is. Pott's method of treatment is not calculated to prevent the falling-in of the lower extremity of the fibula towards the tibia. In a fracture of the lower end of the fibula, when the foot is brought into the state of extreme adduction, it draws by means of the lateral ligaments the point of the outer malleolus in an inward direction, and, consequently, the fractured portion corresponding to it is drawn outwards from the tibia. It is on this principle that Dupuytren's mode of treating this accident is founded. In all cases, then, a fracture of the fibula, accompanied with distortion of the foot outwards, requires an apparatus which maintains the foot turned inwards, and the inferior fragment of the fibula raised from the tibia, and in the direction of the superior fragment. The simple

apparatus recommended by Dupuytren is as follows: a cushion, a splint, and two bandages are the whole of it. The cushion, made of linen, and stuffed two-thirds full of hair-balls, or chaff enclosed in bags in the usual manner, should be two feet and a half in length, four or five inches in breadth, and three or four inches in thickness. The splint is to be from twenty to twenty-three inches in length, and three inches broad. Lastly, the two rollers should each be from four to five yards in length. The cushion, doubled in the form of a wedge, should be applied on the internal side of the fractured limb, its base below, and resting on the internal malleolus, without passing beyond it; its summit above on the internal condyle of the femur. The limb is thus protected from the splint, which derives from the pad a support that keeps it at the distance of several inches from the internal margin of the foot, and at the same time tends to throw the tibia outward. The splint, applied along the cushion, should extend six or seven inches below it, which will be about four inches below the internal margin of the foot. These parts of the apparatus being thus disposed, should then be fixed by one of the bandages passed round the limb below the knee, when the portion of the splint extending below the cushion will leave between itself and the foot an interval of several inches, and furnish a *point d'appui* to which the foot may be drawn from without inwards. In order to effect this purpose, the second bandage should be drawn from this point over the instep and heel, alternately embracing the splint and the parts of the limb just indicated, in circles gradually lessening, and forming the figure of the cipher 8 with the crossing part on the splint. Thus the apparatus acts on the principle of a lever of the *first kind*, in which the *point d'appui* is the base of the cushion, a little above the malleolus internus, and in which the resistance, as well as the power acting on the fracture, are in the extremities of the foot. The foot thus drawn must yield to the action of the lower bandage, while the tibia, pressed by the base of the cushion, must be propelled outwards with the astragalus. Lastly, it is evident that as the lower fragment of the fibula is drawn downwards by the external lateral ligaments of the ankle, a tilting movement must be produced on the external surface of the astragalus, contrary to that which displaced it. With the view of obtaining a complete reduction, Dupuytren says that the surgeon must not confine himself to drawing the foot in a perpendicular line under the limb; it must be brought as much inwards as it had been turned outwards by the peronæal muscles.

After the foot has been retained a good while in this forced state of adduction, if it should not return to its ordinary position, the defect may be easily remedied by applying the preceding apparatus to the outer surface of the leg and foot.

When, with a fracture of the fibula, the foot is drawn backwards and upwards, Dupuytren applies the splint and cushion to the back part of the leg down to the heel. One roller is applied below the knee, and a second round the lower end of the tibia and splint. A square pad should always be put between the lower bandage and the tibia. Of 207 cases of fracture of the fibula, comprising all the varieties of this accident treated in the above way by Dupuytren, 202 were cured; the remaining five died, three of them from the consequences

of the injury itself, or from complications independent of it.

[In a fracture without displacement of the foot or at the seat of fracture, it matters little what apparatus is employed; lateral splints or M'Intyre's apparatus, succeeded in a few days by the starch bandage, will answer every indication. Indeed, in all cases, whether with or without displacement, M'Intyre's splint, or Liston's modification, is as convenient and effectual an apparatus as can be desired. (See *Dislocations of the Ankle-joint.*)]

[FRACTURES OF THE ASTRAGALUS.]

[A fall from a height upon the foot occasionally produces a fracture of this bone, but it is a rare form of accident. In a simple fracture, the fragments are not usually displaced, and, beyond a general swelling of the ankle, there is no evidence externally of the nature of the injury, which is likely to be mistaken for a sprain. Mr. Lonsdale mentions a case in which the bone was broken into several pieces, and the patient was treated for a severe sprain, there being no reason to suspect a fracture, which was only discovered after the death of the patient, which took place on the twelfth day, from the severity of the symptoms which ensued. (*Treatise on Fract.* p. 531.) The fracture may take various directions. M. Malgaigne met with a case in which it was transverse, the bone being divided into an anterior and posterior half. He also mentions a case under M. Taignot where the fracture was in the antero-posterior direction, with incomplete fracture of the neck of the bone. Sir A. Cooper mentions one in which the bone was broken almost horizontally into an upper and lower portion. This was a compound dislocation, and the lower ends of the tibia and fibula, with the upper division of the astragalus, protruded through the skin at the outer side of the ankle. It was found necessary to remove this part of the bone before the dislocation could be reduced, but the patient ultimately did well; an artificial joint was formed, and he recovered with a very good use of his foot. (See Sir A. Cooper, *On Dislocations, &c.* ed. by B. Cooper, p. 290.) A case has been already referred to (see art. DISLOCATIONS, ante, p. 582), in which the body of the astragalus was separated by fracture from the head and neck, and was dislocated forwards upon the tarsus. The dislocated portion, which was loose, was removed through the wound on the dorsum of the foot, and the patient recovered the almost perfect use of his foot.]

[FRACTURES OF THE OS CALCIS.]

[Fractures of the os calcis may be produced in two ways,—by muscular action, and by direct violence, such as a fall on the heel.

Of the *fracture by muscular action*, two cases are mentioned by Sir A. Cooper. The first was that of a lady who when walking in a field stumbled and fell, and was for some time unable to rise. The os calcis was found to be fractured, and its posterior part was drawn up by the action of the gastrocnemius to three inches from its situation. She was very unruly, and would not submit to the appropriate treatment; the bone therefore remained in this position, and the interspace was filled up by ligamentous substance. By wearing a high-heeled shoe, and with the aid of a stick, she was, however, able to bend and extend the foot, and to walk tolerably

well. The second case was that of a lady under the care of Mr. Green, who fractured the bone by the violent action into which the muscles of the leg were thrown in her efforts to preserve herself from falling downstairs. A high-heeled shoe was used for the purpose of keeping the tendo Achillis in its most complete state of relaxation, but ligamentous union only could be effected. (See Sir A. Cooper, *On Dislocations, &c.* ed. by B. Cooper, p. 339.)

In these, and in most other cases which have been recorded, the situation of the fracture is not sufficiently explained; it does not appear whether any considerable portion of the bone was detached, or whether merely the surface into which the tendon is inserted was torn off. There will not be much difficulty in ascertaining the nature of the injury; the separated portion will be readily felt, drawn up by the muscles of the calf to a greater or less extent. Ligamentous union was the result in the two cases which have been mentioned, but in others which have been recorded osseous union was obtained, and there appears to be no difficulty in the consolidation, if the fragments can be maintained in contact or nearly so. The treatment consists in relaxing as much as possible the muscles of the calf, and to effect this the leg must be bent on the thigh, and the foot be extended on the leg. A convenient apparatus for the purpose consists of a slipper, to the posterior part of which a strap is attached, which is passed up behind the leg and fastened to a broad leather belt which is buckled round the lower part of the thigh. The resulting inconvenience does not appear to be great, even if osseous consolidation is not obtained, but the patients are able to walk with the aid of a high-heeled shoe, and sometimes even without this assistance, nearly as well as before.

In the fracture from *direct violence*, the bone is usually more or less comminuted, and M. Malgaigne, who was the first to call attention to this form of injury, speaks of it as the "*fracture par écrasement*." It is more frequent, he thinks, than the fracture by muscular action. It is almost always produced by a fall on the heel, and the bone is broken into several pieces, which may be impacted into each other, so that the breadth of the bone is increased, but its height is diminished. This fracture is situated chiefly in the sub-astragaloid portion of the bone, while the fracture by muscular action always occupies that part which is posterior to the astragalus. The symptoms, as described by M. Malgaigne, are a severe pain in the part, and a swelling which is rapidly developed around the two malleoli, the instep, part of the dorsum of the foot, the two sides of the foot beneath the malleoli, and part of the sole, while, singularly enough, the heel and the region of the tendo Achillis are exempt from it. This swelling masks the deformity of the parts, but on examination it may be felt to be soft opposite the malleoli, while under the malleolus internus the finger rests upon an abnormal projection formed by the lesser process of the os calcis. Crepitus is obscure and sometimes absent; the best way to obtain it is by lateral or twisting movements of the os calcis. The characteristic deformity is an increased breadth of the os calcis, a diminution of the arch of the foot, and in some cases an increased prominence of the heel. The fracture is usually confined to the os calcis, and rarely if ever complicated

with fracture of the astragalus or malleoli. M. Malgaigne mentions two cases in which both calcanea were simultaneously fractured. (See *Traité des Fract.* t. i. p. 831.) A case of fracture of the os calcis from a fall on the heel, which was under the care of Mr. Ure at St. Mary's Hospital, has been recorded by Mr. Gascoyen, then one of the house-surgeons. The fracture was situated beneath the astragalus, at about the junction of the posterior two-thirds with the anterior third of the bone. There was unnatural mobility of the heel, and crepitus was obtained by moving it laterally, and also by holding the heel and flexing the ankle. The parts were kept steady by pasteboard splints, but he was unable to walk at all till more than six weeks after the accident, and it was not till the end of three months that the splints could be dispensed with. At that time firm union was found to have taken place, with a great deposit of callus below and in front of the malleoli, which somewhat interfered with the movements of the joint. Mr. Gascoyen mentions two other cases of fracture of the os calcis from falls on the heel treated at St. Mary's Hospital; in one the fracture was situated at the junction of the posterior two-thirds with the anterior third of the bone, in the other the posterior and upper extremity was separated from the rest of the bone. (See *Med.-Chir. Trans.* vol. xxxix. p. 282, 1856.)

In this form of fracture, the heel is not usually displaced by the action of the muscles of the calf; the apparatus, therefore, which has been recommended for the fracture by muscular action, is not required. It is sufficient to keep the foot quiet by means of lateral splints, or on a M'Intyre's apparatus, till the inflammation has subsided, and then to encase it in pasteboard until consolidation has taken place. Some stiffness of the neighbouring joints will remain for a longer or shorter period.]

[FRACTURES OF THE METATARSAL BONES, AND OF THE PHALANGES OF THE TOES.]

[Fractures of the metatarsal bones are rare; they are usually produced by direct violence applied to the dorsum of the foot. They are often compound and comminuted, and the injury of the bones and soft parts may be such as to necessitate amputation. There may be little or no displacement, especially if only one or two of the central bones are broken; but when it does take place the anterior fragments are usually depressed towards the sole of the foot.

The foot should be kept at rest, and steadied by a splint of pasteboard or gutta-percha; if the displacement just alluded to should be present, an attempt may be made to remedy it by making pressure with a compress on the sole of the foot.

Fractures of the phalanges of the toes are usually compound or comminuted, and require amputation. In a simple fracture, a narrow bandage stiffened with starch will answer every purpose. In a compound fracture, when there is hope of saving the toe, it should be fixed upon a narrow splint of pasteboard or wood placed under its plantar surface. Several writers have remarked that fractures of the great toe are often followed by symptoms disproportionately severe, such as swelling of the foot and leg, inflammation of the absorbents, the formation of abscesses, &c.]

FRÆNUM LINGUÆ. In infants, the tongue is sometimes too closely tied down, by reason of the frænum being extremely short, or continued too far forwards. In the latter case, the child will not be able to use its tongue with sufficient ease in the actions of sucking, swallowing, &c., in consequence of its point being confined at the bottom of the mouth. Though this affection is not unfrequent, it is less common than is generally supposed by parents and nurses. When the child is small, and the nurse's nipple large, it is common for her to suppose the child to be tongue-tied, when, in fact, it is only the smallness of the child's tongue that prevents it from surrounding the nipple, so as to enable it to suck with facility. Mothers also commonly suspect the existence of such an erroneous formation whenever the child is long in beginning to talk.

The reality of the case may always be easily ascertained by examining the child's mouth. In the natural state, the point of the tongue is always capable of being turned upward towards the palate, as the frænum does not reach within a quarter of an inch of the lower part of the tongue from the

apex. But, in tongue-tied children, by looking upon one side, we may see the frænum extending from the back part to the very point, so that the whole length of the tongue is tied down, and unnaturally confined.

The plan of cure is to divide as much of the frænum as seems proper for setting the tongue at liberty. The surgeon presses up the tongue against the palate with his left thumb and fore-finger. The incision should be directed downwards, away from the tongue, and not be carried upward or backward, lest the raninal veins or arteries be cut; an accident that has been known to prove fatal. For the same reason, the scissors used for this operation should be blunt-pointed. If the fore-finger and thumb prevent the parts from being seen, the tongue must be pressed up with a spatula, or a director, that has a slit in which the frænum may be placed, as long ago preferred by J. L. Petit. (See *M. Velpeau*, in *Nouv. Elém. de Méd.* op. t. ii. p. 67, 8vo. Paris, 1832; and *M. Malgaigne*, *Manuel de Méd. Opér.* p. 465, ed. 2. 12mo. Paris, 1837.)

I think the following piece of advice, offered by a modern author, may be of service to practitioners who ever find it necessary to divide the frænum linguæ: "It is not the relations of the trunk of the lingual artery alone, which the student ought to make himself acquainted with. He will do well to study the position of the arteria ranina in respect to the frænum linguæ. This information will teach him the impropriety of pointing the scissors upward and backward when snipping the frænum; an operation, by the by, oftener performed than needed. He will learn that the ranular artery lies just above the attachment of the frænum; so that, if he would avoid it he must turn the points of the scissors rather downward; if he do not, the artery will probably suffer." (*A. Burns*, *Surgical Anatomy of the Head and Neck*, p. 239.)

When an infant has the power of sucking, this proceeding should never be resorted to, even though the frænum may have the appearance of being too short, or extending too far forwards. (*Fab. Hildanus*, centur. iii. obs. 28. *Petit, Mal. Chir.* t. iii. p. 265. edit. 1774.)

Although the operation of dividing the frænum linguæ is, for the most part, done without any bad consequences, surgeons should remember well that it is liable to dangers, especially when performed either unnecessarily or unskilfully. Besides the fatal events which have occasionally resulted from wounding the raninal arteries, the records of surgery furnish us with proofs that the mere bleeding from the raninal veins, and the small vessels of the frænum, may continue so long in consequence of the infant's incessantly sucking, as to produce death. In such cases the child swallows the blood as fast as it issues from the vessels, so that the cause of death may even escape observation. But if the body be opened, the stomach and intestines will be found to contain large quantities of blood. (See *Dionis*, *Cours d'Opérations de Chirurgie*, 7e Démonstration. *Petit, Maladies Chir.* t. iii. p. 282, &c.)

Another accident, sometimes following an unnecessary or too extensive division of the frænum, consists in the tongue being thrown backward over the glottis into the pharynx, where it lies fixed, and causes suffocation. The observations of

Petit on this subject are highly interesting. (See *Op. cit.* t. iii. p. 267, &c.)

Lastly, it should be known that an infant's inability to move its tongue, or suck, is not always owing to a malformation of the frænum. Sometimes the tongue is applied and glued, as it were, to the roof of the mouth, by a kind of mucous substance; and in this case it should be separated with the handle of a spatula. By this means infants have been saved which were unable to suck during several days, and were in imminent danger of perishing from want of nourishment. (See *Mém. de l'Acad. de Chir.* t. iii. p. 16. ed. 4to.)

FRAGILITAS OSSIUM. A morbid brittleness of the bones. Although it may take place at different periods of life, it is remarked to be more common in childhood and in persons of advanced age. (See *B. Bell*, *On Diseases of the Bones*, p. 74.)

Boyer imputes *mollities ossium* to a deficiency of lime in their structure; *fragilitas ossium* to a deficiency of the soft matter naturally entering into their texture. This is not the view usually adopted. One modern writer considers preternatural brittleness and flexibleness of the bones as the results of different degrees of the same cause. One degree produces brittleness; a greater degree flexibleness, with greater brittleness; the most aggravated form, *mollities ossium*. (See *Mayo's Human Pathology*, p. 19.) The diseases termed *rickets* and *mollities*, however, as we shall find by a reference to those articles, are at all events combined with other pathological changes and circumstances. Boyer states that a certain degree of *fragilitas ossium* necessarily occurs in old age, because the proportion of lime in the bones naturally increases as we grow old, while that of the organised part diminishes. Hence the bones of old persons more easily break than those of young subjects, and are longer in uniting again. In old age the cortex of the bones is thinner, and both in it and the cancelli the quantity of phosphate of lime diminished. This is one cause of the frequency of fracture of the neck of the thigh-bone in elderly persons. (See *Mayo*, op. cit. p. 17.) As Mr. Wilson observes, however, they never are found so friable and fragile as to crumble like a calcined bone, but, on the contrary, they contain a large quantity of oil; a fact particularly noticed by Saillant (see *Hist. de la Société de Méd.* 1776, p. 316); and when dried after death, they are so greasy as to be unfit to be preserved as preparations. Their organised vascular part is diminished, but their oily animal matter is increased. (*Wilson*, *On the Skeleton and Diseases of Bones*, p. 258.)

In persons who have been long afflicted with cancerous diseases, the bones sometimes become as brittle as if they had been calcined. Saviard and Louis relate cases of this description. (*Obs. Chir. et Journ. des Savans*, 1691. *Obs. et Remarques sur les Effets du Virus Cancereux*. Paris, 1750. *Pouteau*, *Œuvres Posthumes*, t. i.) Two remark-

able instances of this kind were published by Mr. Salter of Poole. In the first, the patient, a female aged 82, felt the right thigh suddenly break as she was standing at her drawers. For several months previous to the accident she had had constant and very severe pain in the part of the bone which was broken, and she had been long afflicted with a cancerous ulceration of the mamma. After death the bone was so flexible that no bony union could have taken place. A regular dissection of the limb was not allowed. In Mr. Salter's second case, the patient was also a female, 56 years of age, and, for five months preceding the accident, had laboured under violent pain of the right thigh, and a thickening of the periosteum a little above the patella. As her friends were putting her into a cart, the bone snapped about three inches below the trochanter. For several years she had had a scirrhus of the left breast. This had been removed and the wound healed, but afterwards broke out in the form of cancerous ulceration. In this stage the fracture took place, and was followed in about three months by her death. Mr. Salter removed the thigh-bone, and brought it home for examination; but previously to its removal, the affected limb was observed to be considerably shorter than the other, and flexible at its middle, and a good deal deformed by a projection just below the trochanter major. The muscles of the thigh were pale and shrunk; a bloody fluid escaped from the capsular ligament of the knee-joint, and two or three clots of pure blood were in the articular cavity. On removing the patella, a small ulcer was discovered in the upper and external part of its articular surface. The thigh-bone was remarkably soft throughout its whole length, and the knife could be pushed through it at any part, but at its middle it was most conspicuously deficient in earthy matter. At about three inches from either extremity it could be bent in any direction; and it was on the upper part of this portion that the fracture had taken place; but the precise situation of it was not distinctly visible, and Mr. Salter conceives that there had been no complete separation, like what occurs in common fractures. The distortion did not arise from any overlapping, but from a bending of the bone. The muscles about the upper part of the limb were confounded together into an uniform mass of a pale red colour, firm and cartilaginous, with bony spicula thickly dispersed through them, and puriform matter slightly tinged with blood issuing from the cut surfaces. The integuments had suffered no change. In the situation of the swelling noticed above the patella, the tendon of the cruralis was much thickened and altered in texture, and a considerable quantity of pus came from under it; the subjacent periosteum was also much thickened, and readily detached. The parietes of the bone were here nearly absorbed, and the medullary cavity was filled with a bloody pultaceous substance. (See *Med. Chir. Trans.* vol. xv. p. 186.) It is justly inferred by Mr. Salter, that, as these cases correspond in so many points, the predisposing cause of fracture was probably the same in both. Both the patients laboured under cancer of the breast; and both suffered much from previous pain and lameness. These cases, it is to be remarked, were rather specimens of mollities ossium, or preternatural flexibility of the bones affected; and seem to have differed

from some examples of fragility on record, not only in their cause, but in the circumstance of no attempt at ossification having taken place in the broken or flexible parts. They resemble in some respects Mr. Howship's case; yet differ in the affection being restricted to one bone, and being the sequel of a cancerous disease of the breast. In University College Hospital, I remember a woman who had long laboured under cancer of the breast, and in whom several spontaneous fractures had occurred at different periods. She was treated in this hospital, first for a fracture of the humerus, and afterwards for one of the clavicle. In this case every fracture ultimately united.

M. Louis mentions a nun who broke her arm by merely leaning on a servant; and in the *London Medical Journal* an account is given of a person who could not even turn in bed without breaking some of his bones. One of Professor Gibson's patients, residing near Trenton in the United States, has a son, 19 years of age, who from infancy has been subject to fractures from the slightest causes, owing to an extraordinary brittleness of the bones. "The bones of the arm, fore-arm, thigh, and leg, have all been broken repeatedly, even from so trivial an accident as catching the foot in a fold of carpet whilst walking across the room. The clavicles have suffered more than any other bone, having been fractured eight times. What is remarkable, the boy has always enjoyed excellent health, and the bones have united without difficulty or much deformity." (*Institutes, &c. of Surgery*, vol. i. p. 370.)

Similar cases are mentioned by Mr. B. Bell. A child, he observes, fractures a limb. The fracture unites, and is consolidated perhaps in less than the usual period. Some time afterwards, on lifting a moderate weight, or on giving the limb a slight twist, it is again broken, and again unites. Mr. Bell saw this occur three times in different parts of the right humerus of a child five years of age, within the short period of eighteen months. "Several similar cases," he says, "have been under my care: in all of them the patients seemed to enjoy robust health, were apparently untainted by scrofula, and their fragile bones united in a shorter space of time than I have generally observed to be the case in individuals whose bones were tougher." (*On Diseases of Bones*, p. 71.) The same author has been able to discern in only two cases of fragility a palpable deviation from the healthy structure of the bones affected. The subject of one case was a gentleman at the middle period of life, who fractured his humerus in unscrewing a music-stool. The fracture was comminuted, and did not unite. The arm was at length amputated by Mr. George Bell at the shoulder. On examining the limb, the muscles around the fractured bone were found in a pulpy state. The bone, surrounded with blood, partly fluid and partly coagulated, was almost friable, and its whole surface perforated by innumerable small, irregularly shaped holes, giving it a reticulated appearance. (Op. cit. p. 72.)

In the latter stages of syphilis the bones sometimes become remarkably brittle. (*Ephem. Nat. Cur.* dec. ii. ann. iii. obs. 112. *Walther, Museum Anat.* t. ii. p. 29.)

In bad cases of scurvy the bones are occasionally so brittle, that they are broken by the slightest cause, and do not grow together again. (*Böttcher*

von den Krankh. der Knochen, p. 68.) In the museum of University College is a specimen of fragility from scrofula; the humerus having broken in two places from merely shampooing the limb.

Dr. Good was once present at a church in which a lady, nearly seventy-two years old, broke both the thigh-bones by merely kneeling down; and, on being taken hold of to be carried away, had an os humeri also broken, without any violence, and with little pain. Hardly any constitutional disturbance ensued, and in a few weeks the bones united. (*Study of Medicine*, vol. v. p. 332. ed. 3.)

The fragilitas ossium of old age is incurable; but, in children, the tendency depends on some other constitutional disease, and can only be cured by a removal of the latter. (See *Boyer, On Diseases of the Bones*, vol. ii.)

For additional remarks on brittleness of bones, see FRACTURE.

FUNGUS. Any sponge-like excrescence. Granulations are often called *fungous*, when they are too high, large, and unhealthy.

FUNGUS HÆMATODES. (From *fungus*, and *αἷμα*, blood.) So named by Hey. *Millike Tumour*; *Monro. Spongoid Inflammation*; *Burns. Soft Cancer*; *Auct. Var. Medullary Sarcoma*; *Abernethy. Fungoid Disease*; *Sir A. Cooper. Matière Encéphaloïde, ou Cérébriforme*; *Laennec. Fungus Medullaris*; *Maunoir. Cephaloma*; *Carswell.*

This disease was formerly generally confounded with hard cancer. The public are indebted to J. Burns, of Glasgow, for the first interesting account of it; and the subsequent writings of Hey, Freer, Laennec, Andral, Carswell, Wardrop, Langstaff, and others, have made us still better acquainted with the subject.

It is unquestionably one of the most alarming diseases incidental to the human body, because we know of no specific remedy for it; and an operation can only be useful (if it can be useful at all) at a time when it is very difficult to persuade a patient to submit to it. Indeed, when the diseased part is within reach of operation, and extirpated at an early period, a recovery hardly ever follows; for experience proves that it is not a disease of a local nature, but almost always extends to a variety of organs and structures at the same time, either to the brain, the liver, or lungs, &c. It is of the utmost consequence to be aware of this fact, since we should otherwise be induced to at-

tempt many hopeless operations, and deliver a prognosis that might cause disappointment and censure. In a large proportion of patients afflicted with fungus hæmatodes, the general disorder of the system is indicated by a peculiarly unhealthy aspect; a sallow, greenish-yellow colour of the skin, which is frequently covered with clammy perspiration; constant troublesome cough; difficulty of breathing, &c.

Fungus Hæmatodes was the name introduced by Hey. J. Burns has called the disease *spongoid inflammation*, from the spongy elastic feel which peculiarly characterises it, and which continues even after ulceration has taken place. The expression, fungus hæmatodes, is by no means an eligible one; because the disease is not always followed by a protrusion of a bleeding mass; never until the disease has reached an advanced stage; and then the substance which projects is not truly a fungus, but the medullary matter itself.

If, with Dr. Carswell, we regard fungus hæmatodes as a species of cancer, then we may comprehend the disease under his general definition of the latter, as consisting in the formation or deposition of a peculiar substance, which presents great variety of consistence, form, and colour; possesses a vascular organisation of its own; gives rise to the gradual destruction or transformation of tissues; affects successively or simultaneously a greater or less number of organs; and has a remarkable reproductive tendency. Dr. Kerr defines fungus hæmatodes "as a morbid condition of the body, evinced by the development of an elastic uneven tumor, or tumors, not painful in their early stage, and becoming so only by implication with surrounding parts; tending to ulceration; and by ulceration presenting to view a soft and spongy fungus, rapid in its growth, readily bleeding in vascular textures, and emitting a peculiar serous discharge, of a very fetid odour, more or less coloured with blood." (*Cyclop. of Pract. Med.* art. *Fungus Hæmatodes*.)

As I have already observed, however, the protrusion is not a fungus, nor is its structure truly spongy; the disposition to hæmorrhage, likewise, depends, as Dr. Carswell has pointed out, less upon the vascularity of the surrounding parts, than upon its own vascularity, and the thinness of the coats of its blood-vessels.

The consistence of fungus hæmatodes, or medullary sarcoma, varies in different cases, and sometimes at different points of the same tumour; being sometimes more dense than brain, or even as compact as boiled udder, while in other instances its softness is equal to that of the foetal brain, or the milt of a fish; neither is the colour always the same in every case; and it is frequently different at various points of the same mass. Generally, it is like that of the medullary substance of the brain; but sometimes it is redder in particular places, or the medullary matter is broken down and blended with blood, and there may then be within the swelling clots of blood. It was the doctrine of Laennec, that the soft consistence of all carcinomatous formations is invariably preceded by a hard condition of them. This opinion is not entirely renounced at the present time, though the investigations of M. Andral and Dr. Carswell clearly prove that it ought to be so. "The carcinomatous deposit, besides being modified in its consistence by the tissues in which it is contained, is equally so in consequence of a difference in its composition; it

may be either hard or soft at this period; and consequently the latter state is not necessarily preceded by the former." (See *Illustrations of the Elem. Forms of Disease*, fasc. iii.) Dr. Carswell illustrates this fact by reference to what happens in the cellular tissue and on serous surfaces; and more especially on the surfaces of sores formed by the destruction of protruded portions of tumors, or after the removal of the breast, eye, or testis, affected with carcinoma. In all these situations, he observes, the deposited substance may present, at the same stage of its formation, the opposite extremes of consistence; being in one case as hard as cartilage, and more or less transparent, and in another, as soft as brain, and quite fluid, and opaque.

One very important pathological fact, in relation to this subject, is the frequency of scirrhus, medullary sarcoma, and fungus hæmatodes, originating in the same morbid state, and passing from one to the other in this order, as specified by Dr. Carswell. Indeed, he adds, we often meet with all the varieties of scirrhus and medullary cancer (termed by him cephaloma), not only in different organs of the same individual, but even in a single organ. I have now seen many cases proving the truth of these statements; yet, probably, the doctrine is correct which represents fungus hæmatodes as a distinct malady, although it may be consequent upon, or complicated with, other alterations of structure. When it occurs in *young* subjects, it is always *primary*, or is not preceded nor attended by the carcinomatous formation. But in persons past the meridian of life, in whom only scirrhus-cancer, or hard cancer, is met with, the fungoid structure is sometimes produced *consecutively*, or in an advanced stage of it, and thus occasionally exists as a secondary complication with that disease, or as one of the advanced changes of structure consequent upon the constitutional vice." (See *Dr. Copland's Dict. of Pract. Med.* art. *Fungoid Disease*.) The same writer adds that, in a few instances, other morbid formations besides this have been found associated with the cerebriform structure, as fibrous tumors, serofulous matters, pus, melanosis, hydatids, and earthy deposits. Dupuytren notices a form of fungus hæmatodes, which is pulsatory, and combined with erectile tissue; which latter circumstance, he says, may render the disease susceptible of a favourable change by the ligature of the artery, whose branches keep up the circulation in it; while the other elementary matters found in it, in greater or lesser quantity, as the scirrhus and cerebriform, are a great impediment to the success of this method of relief. (See *Clin. Chir.* t. iv. p. 59., and *Andral, Anat. Pathol.* t. i. p. 219.) The blood-vessels which enter scirrhus and medullary sarcoma vary greatly in number, and sometimes considerably in bulk. They are rarely perceptible in any of the varieties of scirrhus, and are but few in the organised and mammary sarcoma, which are considered by Dr. Carswell as varieties of medullary sarcoma (cephaloma); while, in ordinary medullary sarcoma, they are often so numerous as to form the greater portion of the brain-like tumor in which they ramify. In this disease they are described by the latter eminent pathologist as varying in diameter from the breadth of a hair to that of a line, and to present that peculiarity of distribution, always more or less conspicuous in newly-formed blood-vessels,

which is, that their ramifications communicate with a common trunk at its opposite extremities, in the same manner as the hepatic and abdominal divisions of the vena portæ do with the trunk of this vessel. They are frequently varicose; their coats are remarkably delicate, and they have altogether much more of a venous than of an arterial character. According to Dr. Carswell's researches, they appear to be formed apart from the vascular system of the surrounding textures, as they can be seen to originate in small red points, situated at the centre or at the circumference of the carcinomatous mass, which first assume the appearance of slender streaks of blood, and afterwards acquire a cylindrical arrangement and ramiform distribution, thereby constituting what may be denominated the *proper circulation* of medullary sarcoma, or cephaloma. The communication between these vessels and those of the organ in which the medullary substance is contained, is frequently very imperfect; a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The most minute divisions of these vessels terminate by pencillated extremities in the carcinomatous matter, where they communicate with veins and arteries belonging to the affected organ. The latter vessels, which Dr. Carswell regards as forming what may be termed the *collateral circulation* of medullary sarcoma, are seldom so conspicuous as the former; though cases now and then occur in which they constitute the greater part of the vascular structure of the disease. They are described by the same excellent pathologist as proceeding in a radiating direction from the pedunculated attachment of a tumor, or as rising along its circumference in the cellular tissue, separating it from the neighbouring parts. It is, he observes, by means of these vessels that the materials required for the nutrition and growth of such tumors are supplied; and causes interrupting this collateral circulation will occasion the partial or complete destruction of these and other tumors. (See *Carswell's Illustrations of the Elem. Forms of Disease*, fasc. iii.)

According to the same high authority, nerves have never been detected in this or any other variety of cancer as a *new formation*, though they are sometimes included within agglomerated tumors, or even a single tumor, that has happened to form in a situation through which they pass. In some cases the nerves have participated in the change of structure; but, according to Dr. Copland, they have not been found changed beyond the limits of the tumor. In the eye the structure of the optic nerve is constantly altered; and in a case referred to by Mr. Wardrop, the anterior crural nerve passed into the centre of the diseased mass, and was so completely lost in it that it was impossible to distinguish one structure from the other. Observations of this kind led M. Maunoir to suppose that the medullary matter was actually a collection of nervous pulp, an idea very inconsistent with the well-known insensibility of such medullary matter. M. Lobstein, in combating the doctrine of M. Maunoir, declares that he has seen cases in the early stage of which the nerves passed through the tumor without undergoing any change.

A very common character of medullary tumors is to be lobular, the lobules being closely compacted together and enclosed in remarkably fine cysts, the presence of which may be demonstrated

by macerating the soft substance and washing it away, or dissolving the medullary matter with the aid of alkalies. This lobulated and encysted structure is generally noticed in cases where the tumor is near the surface of the body. These cysts, in which the medullary matter is often contained, are externally fibrous and cellular, but internally they present, as Dupuytren remarks, a completely serous organisation, and here a serosity exhales from them. Sometimes the medullary matter originates from, and is adherent to, a single point of the cyst; while in other instances it adheres almost to every part of the interior of the cyst, which is itself closely connected to the surrounding textures. Under these circumstances the cyst is fibro-cellular or entirely fibrous. (See *Dupuytren, in Clin. Chir. t. iv. p. 57.*)

Dr. Hodgkin has advanced the doctrine that the presence of a serous membrane having a cystiform arrangement, is necessary for the production of cancerous and some other kinds of tumors. The existence of the cyst, he believes, precedes the formation of the morbid substance, and constitutes the seat and origin of the disease. (See *Med. Chir. Trans. vol. xv.*) Although Dr. Carswell admits that this mode of origin is sometimes exemplified, he mentions facts which leave no doubt that it is only accidental and not essential. Cysts, he observes, partake of the structure and functions of serous membrane, and consequently are subject to similar diseases. "If therefore such cysts should exist in an individual having the cancerous diathesis, they may in the same manner as a natural serous membrane become the seat of any variety of carcinoma. But although carcinomatous tumors, such as those described by Dr. Hodgkin, are found contained in cysts, attached, single, or in groups, and covered by a reflected serous membrane, these tumors may, and frequently do, not originate in the cysts. They may form in the cellular tissue external to the cysts, and during their development project inwards, carrying before them, as their common envelope, the internal and serous lining of the latter. Such, in fact, is seen to be the origin of these tumors in most of the cysts represented by Dr. Hodgkin in the work referred to. They are situated external to the cyst, are supplied with vessels which do not belong to it, and are placed in the same circumstances as tumors formed in the cellular tissue when no cyst is present.

"As an objection to the general application of the cystic origin of tumors, it may be observed that the presence of cysts in the liver, walls of the stomach, lungs, kidneys, brain, lymphatic glands, spleen, and blood, is not to be detected at any period of the development of carcinoma; and therefore, when they do occur in other organs, as the ovaries, testes, mammae, &c., they must be regarded as a mere coincidence, or as a consequence of the disease, and not as a cause or necessary condition of it." (See *Carswell's Illustrations of the Elem. Forms of Disease, fasc. ii.*)

A very interesting fact in relation to fungus hæmatodes, or medullary sarcoma, is that of the occasional presence of the cerebriform substance in the veins and absorbents. A similar fact is noticed with regard to scirrhus cancer. Dr. Carswell believes that the carcinomatous and medullary matter is formed in the blood, whether met with in this fluid alone or in other parts at the same

time, and he supports his view upon the facts—1st, that the morbid substance is found in the vessels which ramify in these malignant tumors or their vicinity. 2dly, That it is found in those vessels which communicate with the diseased parts of an organ. 3dly, That it is sometimes met with in vessels having no direct communication with another part that is the seat of the same disease. After noticing that the venous and capillary divisions of the vascular system are those in which the carcinomatous substance has been observed, Dr. Carswell describes the forms under which it appears in the blood, and which are exceedingly various; "sometimes perfectly similar to those which mark its presence in the substance or on the surface of organs. In large veins, such as the vena portæ and its branches, the emulgent vein, &c. it may present the lardaceous, mammary, medullary, or hæmatoid characters, all in the same venous trunk. These varieties of the carcinomatous formation may be found mixed together in minute quantities, or isolated into masses so conspicuous, that we can readily distinguish them from one another. Sometimes they lie merely in contact with the internal parietes of the vein; at other times they are united to the latter by means of a thin layer of colourless fibrine; or minute blood-vessels pass from the one into the other, and are often very numerous, and remarkably conspicuous in the cerebriform matter." It seems to Dr. Carswell that the presence of an organised product in the blood can have no other origin than the blood itself, and that such a product cannot be introduced into this fluid by absorption. (See *Illustrations of the Elem. Forms of Disease, fasc. ii.*)

By some pathologists a different view is taken of this part of the subject, and they maintain that, when the carcinomatous or medullary matter is found in the blood, it has been absorbed. On this principle, the extension of the disease is even attempted to be in part accounted for. But the frequently organised state of the product in the blood, and its occasional existence there without any traces of a similar formation in any other part of the system, are arguments strongly confirming the accuracy of Dr. Carswell's statements. This gentleman's doctrine is not, however, universally adopted. Thus, Dr. Copland observes that the formation of the cerebriform matter in the blood, and its subsequent deposit in the parts which are its seats, "cannot be supported by the history and progress of the local and constitutional affections. If it were previously formed in the blood, wherefore is it often deposited only in one situation? Wherefore is it not excreted by the emunctories? Wherefore does it not always affect a number of parts simultaneously? Wherefore is it never found in the arteries, and so frequently in the absorbents and veins proceeding from the seat of the disease?" These and other questions, Dr. Copland maintains, cannot be answered consistently with Dr. Carswell's doctrine. (See *Dict. of Pract. Med. art. Fungoid Disease.*) With respect to the medullary substance never being met with in the arteries, Mr. Hey states, that in a case of fungus hæmatodes of the thigh, "the femoral artery was filled with matter, resembling stiff coagulated blood, which prevented the blood from flowing through the divided vessel."

According to the researches of Lobstein, the firmer

FUNGUS HÆMATODES.

the tumor, and the earlier the stage of it, the greater the proportion of gelatine to the albumen in it. On the other hand, when the morbid substance is of the consistence of soft brain, the albumen in it is in much greater quantity than the gelatine. I have already explained, however, that the firm and soft conditions of the disease are by no means any certain proof of its early and advanced stages, since the morbid substance is frequently from the first of the same consistence which it exhibits in the end.

Fungus hæmatodes, or medullary cancer, is much more frequently met with in young than old persons; children of the most tender years being often its victims. I am not aware of any records by which a judgment might be formed of the comparative frequency of the disease in the two sexes. In my practice, more instances of it, in external situations, have presented themselves in males than females. The testis, as is universally acknowledged, is oftener the seat of it than the mamma. Speaking of it, however, more generally, I can offer no opinion of its comparative frequency in the two sexes. Dr. Kerr leans to the supposition that females are more frequently the subjects of it than males. (See *Cyclop. of Pract. Med.* art. *Fungus Hæmatodes*.)

It is a common remark that the persons whom it attacks are generally of a sallow complexion, lax fibre, and weak circulation. Yet, when the disease is in the early stage, and limited to some external situation, as, for instance, to one of the limbs, there may be no other apparent fault in the health; and the patient may be neither sallow nor debilitated. A fine stout healthy-looking lad was brought a few months ago to University College Hospital, who had a medullary tumor as large as an orange upon the lower border of the latissimus dorsi. The same case exemplified also one character of medullary tumors meriting particular notice, viz. the extraordinary rapidity with which they sometimes increase, even though the skin may not have ulcerated. In this boy the tumor which I have mentioned enlarged so much in the course of a week, that it not only extended completely across the axilla, but far up into its cavity. But the progress of the disease is not always quick; and at one time it may be very slow, and at other periods surprisingly rapid. Generally, when it is liberated from a part of its coverings by ulceration, or when it returns in a part in which an attempt has been made to extirpate it by operation, the growth of the protruding medullary mass is very quick.

Fungus hæmatodes has frequently attacked the eyeball, the upper and lower extremities, the testicle, and the mamma. But the uterus, ovary, liver, spleen, brain, lungs, thyroid gland, hip and shoulder joints, and various other parts and organs, may be seats of the disease.

It is in this medullary form of disease that a vascular organisation is most conspicuous; and as the coats of the vessels with which it is supplied are remarkably delicate, the circulation of the blood through them is readily interrupted; hæmorrhage from congestive rupture takes place; and the effused blood is mixed in less or greater quantity with the brain-like matter. (See *R. Carswell's Illustrations of the Elem. Forms of Disease*, fasc. ii.) The appearances thus produced are termed hæmatoid. By M. Roux, Dr. Carswell, and all writers who employ the expression *soft cancer*, fungus hæmatodes,

or medullary sarcoma, is regarded either as closely allied to cancer, or as actually a variety of it. Under the generic term of carcinoma, indeed, Dr. Carswell comprehends scirrhus; the common vascular or organised sarcoma of Abernethy; also his pancreatic, mammary, and medullary sarcoma; and fungus hæmatodes, or the latter disease in an advanced stage, with a portion of the mass of the disease protruding. Dr. Carswell's reasons for this classification are:—1st, That all these diseases "often present, in the early periods of their formation, certain characters common to all of them. 2ndly, They all terminate in the gradual destruction, or transformation, of the tissues which they affect. 3rdly, They have all a tendency to affect several organs in the same individual. 4thly, They all possess, although in various degrees, the same reproductive character." When medullary cancer is not of immoderate size, and situated directly under the integuments, its surface is generally at first smooth, but after a time uneven, or lobulated; the colour of the skin not altered; the part has a soft elastic feel; and it seems as if an indistinct fluctuation were perceived in it.

FUNGUS HÆMATODES OF THE LIMBS.

In the extremities the disease begins with a small colourless tumor, which is soft and elastic if there be no thick covering over it, such as a fascia: but otherwise it is tense. At first it is free from uneasiness; but by degrees a severe acute pain darts occasionally through it, more and more frequently, and at length becomes incessant. For a considerable time the tumor is smooth and even; but afterwards it projects irregularly at one or more points; and the skin at these places becomes of a livid red colour, and feels thinner. In this situation it easily yields to pressure, but instantly bounds up again. Small openings now form in these projections, through which is discharged a thin bloody matter. Almost immediately after these tumors burst, a small fungus protrudes, like a papilla, and this rapidly increases both in breadth and height, and frequently bleeds profusely. The matter is thin, and exceedingly fetid, and the pain becomes of the smarting kind. The integuments, for a little way round these ulcers, are red and tender. After ulceration takes place, the neighbouring glands swell, and assume exactly the spongy qualities of the primary tumor. If the patient still survive the disease in its present advanced progress, similar tumors form in other parts of the body, and the patient dies hectic.

After death or amputation the tumor is found to consist of a soft substance, somewhat like the brain, of a greyish colour and greasy appearance, with thin membrane-like divisions running through it, and cells, or abscesses, in different places, containing a thin bloody matter, occasionally in very considerable quantity. There does not seem uniformly to be any entire cyst surrounding the tumor; for it very frequently dives down betwixt the muscles, or down to the bone, to which it often appears to adhere. The neighbouring muscles are of a pale colour, and lose their fibrous appearance, becoming more like liver than muscle. The bones are mostly carious in the vicinity of the disease.

The growth of medullary tumors near the surface of the body is sometimes preceded by a blow

on the part; but in general the exciting cause is perfectly obscure, the disease appearing to begin spontaneously, though in connection with some unknown peculiarity, or modification of the constitution, without which no circumstances would be capable of inducing it: when we see a patient sallow and enfeebled in this disease, such change of the complexion, and the debility manifested, are not to be regarded as causes, but only as effects of the disease on the general health. (*J. Burns, On Inflammation*, vol. ii.)

Mr. Hey recorded several cases of fungus hæmatodes. If I notice the principal circumstances relative to one of these, they will suffice to inform the reader of the form in which this terrible affliction presented itself in this gentleman's practice.

A young man aged twenty-one, two years before applying to Mr. Hey, perceived a small swelling on the inside of the right knee, not far from the patella. This tumor was moveable, and did not impede the motion of the joint: it was not discoloured, but was painful when moved or pressed upon. It continued in this state half a year; and then, the man having hurt his knee against a stone, it gradually increased in bulk, but did not exceed the size of an egg. The skin was now discoloured with blue specks, which were taken to be veins. He could still walk with ease, and follow his business.

Two months before his admission into the Leeds Infirmary he met with a fall, and violently bent his knee, but did not strike it against anything. The tumor began immediately to enlarge; and within a few hours it extended half way up the inside of the thigh. About a fortnight after this accident the skin burst at the lowest part of the tumor, and discharged some blood. A dark-coloured fungus, about the size of a pigeon's egg, here made its appearance; and, a few weeks afterwards, the skin burst at another part of the large tumor, and some blood was again discharged. From the fissure arose another fungus, which had increased, in the course of the last week, to the size of a small melon, and now measured eight inches from one side of its base to the other. The base of the fungus frequently bled, especially when the man allowed his limb to hang down.

The whole tumor was now of an enormous size, being nineteen inches across, when the measure was carried over the last-mentioned fungus. From its highest part in the thigh to the lowest part, just below the knee, it measured seventeen inches, without including the fungus. The base of the tumor at the knee, exclusive of that part which ran up the thigh, measured twenty-four inches in circumference. The tumor was situated on the inner side of the limb, and was distinctly defined. The skin covering the disease was in some places livid, and had several fissures and small ulcerations upon it; but had not burst asunder, except in the two places above described. The tumor was soft, and gave a sensation of some contained fluid, when gently pressed with the hands alternately in opposite directions. The patient said he had walked without pain in his knee a week before his admission into the infirmary; and he had lost very little blood in his journey to Leeds. He complained of the greatest uneasiness in the highest part of the tumor. It had become hot and painful in the night-time, for some days past. His pulse was 114 in a minute;

his tongue was clean; and his appetite had been good till the last few days. He had never felt any pulsation in the tumor.

In a consultation it was determined that the tumor should be laid open, by cutting off a portion of the distended integuments; and that, after removing the contents, if the sac should be found in a sound state, the disease should be treated as a simple wound; but if in a morbid state, amputation of the limb should be immediately performed.

A large oval piece of the integuments being removed, the tumor was found to contain a very large quantity of a substance not much unlike coagulated blood, but more nearly resembling the medullary part of the brain in its consistence and oily nature. It was of a variegated reddish colour, in some parts approaching to white, and, as blood issued from it, Mr. Hey conceived it was organised. This mass was partly diffused through the circumjacent parts in innumerable pouches, to which it adhered, and was partly contained in a large sac of an aponeurotic texture, which was connected with the capsule of the knee-joint. There was a great and universal effusion of blood from the internal surface of the sac, and from the pouches containing this morbid mass.

On finding such to be the nature of the case, amputation of the limb was immediately performed. Mr. Hey unfortunately, however, left a portion of the diseased surface behind on the inner part of the thigh, and hoping that a small narrow portion of the upper part of the sac would soon become a clean sore, and not impede the cure, he made the circular incision two inches below its higher part.

On examining the amputated limb, the vastus internus was found to be brown, and much softer than the other muscles, which were healthy. There were many small portions of blood extravasated in the substance of this muscle. The sac was formed on the aponeurotic covering of the muscle, and ended below where this aponeurosis begins to cover the capsular ligament of the knee. The two fungous substances above described appeared to have been only extensions of the morbid mass, where this had made its way through the sac and the integuments. The joint of the knee, and muscles of the leg, were perfectly sound.

I need not detail all the particulars after the operation. Suffice it to say the man suffered a great deal of constitutional disorder. After a few weeks, the granulations upon the stump became good, and the cicatrization was nearly completed at the end of the sixth week after the amputation. At this period the small and superficial portion of the upper part of the great sac, which Mr. Hey had unfortunately left, was healed; but a tumor, now about four inches in length, and between two and three in breadth, had gradually risen at the lower and under part of the thigh, beneath the cicatrix. This contained a soft substance, exactly similar, as far as the touch could discover, to that which had filled the large sac. This tumor became painful, and sometimes discharged a bloody serum, sometimes dark-coloured blood, through four or five small openings in the cicatrix.

Mr. Hey laid open the tumor, and removed its contents; but no advantage was gained by this

proceeding. The interior surface was found to be too much diseased to produce good granulations. Blood continued to ooze out of the wound for a few days. Then the inner surface became covered with a blackish substance, which gradually extended itself, and formed a new fungus. A variety of escharotics were applied to destroy the fungous and morbid surface of the wound, but to no purpose; the growth of the fungus always exceeded the quantity destroyed. Undiluted sulphuric acid, applied freely, had very little effect.

An attempt was once more made to cut away the disease; but on examining the wound carefully, after the contained substance was removed, the muscular substance was found degenerated into a hard mass, which felt somewhat like cartilage. The adipose membrane was also diseased, and formed into large cells, which had contained the fungous substance. Hence another amputation seemed the only resource.

After this operation the whole surface of the stump seemed sound, except the principal artery, which was filled with a somewhat stiff matter, resembling coagulated blood, which prevented its bleeding. The inside of the vessel, on being touched with the scalpel, felt hard, and communicated a sensation like that of scraping bone.

The man was sent home as soon as his state would admit of it; but he died consumptive about six months afterwards. Besides this instance, in the thigh, Mr. Hey relates cases of fungus hæmatodes situated in the female breast, in the leg, in the neck (extending from the jaw to the clavicle, and producing suffocation), on the back part of the neck, on the back part of the shoulder, and at the extremity of the fore-arm, near the wrist.

"If I do not mistake (says Mr. Hey), this disease not unfrequently affects the globe of the eye, causing an enlargement of it, with the destruction of its internal organisation. If the eye is not extirpated, the sclerotic bursts at the last, a bloody sanious matter is discharged, and the patient sinks under the complaint." (p. 283.)

Besides some cases in similar situations to those mentioned by Mr. Hey, one is related by Mr. Burns, in which the hip-joint was the seat of this terrible affection. After detailing the progress of the case to the poor man's death, this author states that he found on dissection the hip-joint completely surrounded with a soft matter, resembling the brain, enclosed in thin cells, and here and there cells full of thin bloody water; the head of the thigh-bone was quite carious, as was also the acetabulum. The muscles were very pale, and almost like boiled liver, having completely lost their fibrous appearance and muscular properties. The same sort of morbid mischief was also found within the pelvis, most of the interior of the bones on the affected side being carious. An attempt had been made, before the patient died, to tap the bladder; but the trocar had only entered a cell filled with bloody water, and situated in a mass of the soft brain-like substance.

I have already stated enough in explanation of the dreadful nature of fungus hæmatodes. Little can be said of the treatment; for we know not of one medicine that seems to have the least power of putting a stop to the disease, which, when left to itself, has always proved fatal, with the exception of the rare cures by mortification of the parts,

as illustrated in one example related by Schmidt, where a medullary tumour of the eye mortified, the sloughs were detached, the eyeball collapsed, and a small knob, consisting almost entirely of the contracted sclerotica, was the only remnant of this dreadful form of disease. A case of fungus hæmatodes of the left cheek is alleged, by Dr. Schutte, to have terminated favourably by the process of mortification and sloughing. (See *Grafe's Journ.*) Under Mr. Cline, there was a woman whose breast healed up after the diseased mass had been thrown off by sloughing. (*Lancet*, vol. ii. p. 401.) With a few exceptions of this kind, we have no reason to believe that there is the smallest chance of any spontaneous amendment, much less of a cure. Also, in some of the cases just now cited, it is not known whether any relapse followed.

We have seen that, when the chief part of a fungus hæmatodes is cut away, and only a small portion of its cyst left behind, the fungus is reproduced from this part, and soon becomes as formidable, nay, more formidable, than it was before, and this notwithstanding the application of the most powerful escharotics. Neither the red precipitate, the bichloride of mercury, the antimonium muriatum, nor the undiluted sulphuric acid, have been able to repress the growth of such fungus. (Hey.)

No known remedy has the power of checking or removing the complaint. Friction, with anodyne liniments, sometimes gives relief from pain in the early stages; but it does not retard the progress of the disease. Mercury and iodine have been alleged to do so, but I have never seen an instance of it.

In short, the only chance of cure consists in extirpating the whole of the distempered parts, removing not only the soft, brain-like fungous substance, but every particle of the cysts, sacs, or pouches in which it may be contained. The result of such proceedings is also for the most part unsuccessful, the disease returning in the same situation, or manifesting itself soon afterwards in others. Experience proclaims this discouraging truth so loudly, that many of the best surgeons now decline to undertake any operation in cases of this description; for, if the attempt fails, the patient is put to unnecessary pain, and his life is abridged by the more rapid and deplorable form in which the disease reappears. At all events, an operation is justifiable only in the early stages, while the disease is entirely local, if it ever be so—a circumstance much to be doubted. After the neighbouring glands have become affected, all chance of recovery is destroyed. Nor should the knife be resorted to for the removal of any external medullary tumor, when there is any sign of the existence of other tumors of the same nature in any of the viscera, glands, or other deep-seated organs. It is sometimes difficult to persuade patients, at an early period, to submit to amputation or extirpation, because the pain and inconvenience are not considerable; but if circumstances then warrant the performance of the operation, it should be urged with all the force which a conviction of its absolute necessity, and the fatal peril of delay, ought to inspire.

The attempts to cure a medullary tumor on a limb by cutting it away have been attended with such ill success, that many surgeons deem it advisable not to follow this method, but to ampu-

tate the limb at once. The annexed views of the matter appear to me to be most judicious and rational. First, that if an attempt be made to cut away the tumor, and save the limb, the surgeon must be careful to remove at the same time a considerable quantity of the soft parts in the circumference of the swelling. Secondly, that the earlier this is done, the more likely is it to succeed. Thirdly, that after the tumor has been taken out, an attentive examination of the surface of the wound should be made, and every suspicious part, or fibre, be cut away. Fourthly, that, should the disease still recur, amputation ought to be instantly performed. Fifthly, that caustics should never be applied to this disease. Sixthly, that, even when one of these operations effectually extirpates the distemper in the limb itself, the patient's entire recovery is always rendered exceedingly uncertain, by reason of the viscera, and other deep-seated parts, being frequently affected at the time of the operation with the same sort of disease, which state of them, though invisible, is often denoted by a sallow complexion, debility, indigestion, emaciation, and hectic.

I will quit this part of the subject with stating some of the principal differences between this form of malignant disease and scirrhus. A scirrhus tumor is, from its commencement, hard, firm, and incompressible. A scirrhus tumor situated in a gland is not always capable of being separated from the latter part, so much are the two structures blended. A scirrhus, in another situation, generally condenses the surrounding cellular substance, so as to form a kind of capsule, and assume a circumscribed appearance. When a scirrhus swelling ulcerates, a thin ichor is discharged, and a good deal of its substance is destroyed by the ulceration; other parts become affected, and the patient dies from the increased ravages of the disease, and its irritation on the constitution. Sometimes, though not always, after a scirrhus has ulcerated, it emits a fungus of a very hard texture. Such excrescence, however, is itself at last destroyed by the ulceration. Ulcerated scirrhus sores, also, frequently put on for a short time, in some places, an appearance of cicatrisation. On the other hand, fungus hæmatodes, while of moderate size, is a soft elastic swelling, with an equal surface, and a deceitful feel of fluctuation. It is, in general, quite circumscribed, and often included within a capsule. The substance of the tumor, instead of being for the most part hard, consists of a soft, pulpy, medullary matter, which readily mixes with water. When ulceration occurs, the tumor is not lessened by this process, as in scirrhus; but a fungus is emitted, and the whole swelling grows with increased rapidity. Scirrhus diseases are mostly met with in persons above forty years of age, while fungus hæmatodes generally afflicts young subjects. (*Wardrop*.) Many dissections have now proved that the substance of fungus hæmatodes may contain cellular septa, which include the pulpy, medullary matter.

Fungus hæmatodes, in its early stage, is generally attended with less acute pain than is experienced in cases of scirrhus. The tumor also has a less definite boundary than a scirrhus, and it is more difficult to say where the diseased structure terminates, and where the healthy commences. When the disease is in the breast, there is less tendency than in scirrhus cases to disease in

the axillary glands, which may remain sound, though the disorder in the breast may have advanced to suppuration and ulceration. In the breast the disease is also much quicker in its progress than scirrhus. (*Sir A. Cooper, Lancet*, vol. ii. p. 399.)

In cases of scirrhus, the viscera are not in general affected at the same time with the disease; but in the majority of examples of fungus hæmatodes, this distemper is found affecting in the same subject a variety of parts. In addition to the outward tumor, we find swellings of a similar nature, perhaps, in the liver, the lungs, the mesenteric glands, or even in the brain. [For the position which fungus hæmatodes holds amongst other cancerous diseases, see CANCER.]

FUNGUS HÆMATODES OF THE EYE

Presents three stages. In the first, the exterior form of the eye is unchanged, and the disease is perceived through the cornea and pupil. In the second, the form of the eye is altered; the organ is enlarged, and its tunics are ready to give way. In the third (or *fungous* stage), the eye has burst and the tumor protrudes. (See *MacKenzie on Dis. of the Eye*, p. 647, ed. 2.)

The first symptoms are observable in the posterior chamber, an appearance like that of polished iron presenting itself at the bottom of the eye. (*Scarpa, On Diseases of the Eye*, p. 505, ed. 2.) The pupil becomes dilated and immoveable, and, instead of having its natural deep black colour, it is of a dark amber, and sometimes of a greenish hue. The change of colour becomes gradually more and more remarkable, and at length is discovered to be occasioned by a solid substance, which proceeds from the bottom of the eye towards the cornea. The surface of this substance is generally rugged and unequal, and ramifications of the central artery of the retina may sometimes be seen running across it. The front surface of the new mass at length advances as far forwards as the iris, and the amber, or brown appearance of the pupil, has, in this stage, been known to mislead surgeons into the supposition of there being a cataract, and cause them to attempt couching. The disease continuing to increase, the eyeball loses its natural figure, and assumes an irregular knobby appearance. The sclerotica also loses its white colour, and becomes of a dark blue, or livid hue. Sometimes matter now collects between the tumor and the cornea. The latter membrane in time ulcerates, and the diseased mass begins to protrude. In a few instances, it makes its way through the sclerotica, and is then covered by the conjunctiva. The surface of the excrescence is irregular, often covered with coagulated blood, and bleeds profusely from slight causes. When the fungus is very large, the most prominent parts slough away, attended with a fetid sanious discharge. In the course of the disease, the absorbent glands under the jaw, and about the parotid gland, may become contaminated. On dissection, a diseased mass is found extending forwards from the entrance of the optic nerve, the vitreous, crystalline, and aqueous humours being absorbed. The retina is annihilated, and the choroid coat propelled forwards, or quite destroyed. The tumor seems to consist of a sort of medullary matter, resembling brain. The optic nerve is thicker and harder than natural, of a brownish ash-colour, and destitute of its usual tubular appearance. In other cases the

nerve is split into two or more pieces, the interspaces being filled up with the morbid growth. (*Wardrop*.) Nay, as Mr. Travers has stated, the optic ganglion, tractus opticus, and thalamus, have been repeatedly found diseased, and the surrounding adipose substance in the orbit affected to a considerable extent in places also where there was no direct communication with the diseased contents of the globe. (*Synopsis of the Diseases of the Eye*, p. 221.) Even the brain has been observed to share in the disease, sometimes dark-red spots appearing on the dura mater; sometimes small spots, containing a fluid like cream, being found between the pia mater and tunica arachnoides. Mr. Travers has a preparation, exhibiting a genuine example of the disease affecting the anterior right lobe of the cerebrum, and protruding the eye from its socket, while the eye itself was perfectly free from disease. (*Op. cit.* p. 223.) When the lymphatic glands at the angle of the jaw are enlarged, as they frequently are, they are also found converted into a kind of medullary matter, similar to that which composes the diseased mass in the eyeball. When the skin bursts over a diseased absorbent gland, a sloughy ulcer is produced; but no fungus is emitted, unless the affection of the gland with fungus hæmatodes be primary. In University College Hospital, a poor Irishman was under my care in the autumn of 1836, who had a large medullary tumor, covering all the submaxillary region, and which probably at first had been merely an absorbent gland. In this case, after ulceration of the skin, protrusion of the medullary substance, and sloughing of it, a thin fetid discharge, occasional hæmorrhage, and extreme emaciation and weakness, preceded the patient's death.

Fungus hæmatodes of the eye was formerly not discriminated from scirrhus cancer. We learn from Bichat, that more than one third of the patients on whom Desault operated for *supposed* carcinoma of the eye were under twelve years of age. Twenty out of twenty-four cases of fungus hæmatodes of the eye with which Mr. Wardrop has been acquainted, happened to children under twelve years of age. Now, as scirrhus cancer is rather a disease of aged than young persons, and we find, from Mr. Wardrop, that fungus hæmatodes of the eye mostly affects persons under twelve years of age, it is tolerably certain that most of Desault's cases, reported to be cancers of the eye, were in fact instances of the terrible disease now engaging our consideration. It is observed by Dr. Mackenzie, that the greatest number of cases has been observed in children from two to four years of age. Sometimes the disease occurs a few months after birth. In one instance, he saw it in an infant only nine weeks old, and the mother had noticed it six weeks earlier, so that the disease was probably congenital. On the other hand, it has been known to attack adults, or even persons of advanced age. (See *Mackenzie on Dis. of the Eye*, p. 652, ed. 2.) Another experienced gentleman in this department of surgery, states, however, that he has never yet seen a perfect example of fungus hæmatodes of the eye in an individual more than five years old. (*R. Middlemore on Dis. of the Eye*, vol. ii. p. 388.) According to Mr. Travers, the only parts of the eye and its appendages subject to be primarily attacked by hard cancer, are the lachrymal gland, conjunctiva, and eyelids; while the evidence of many

cases has assured him that fungus hæmatodes may originate in any texture of the eye, with the exception of the lens and cornea. (*Synopsis, &c.* p. 216, 222, and 421.) This account, however, differs from that delivered by Mr. Wardrop and Professor Scarpa, who describe the disease as first commencing in the retina, and particularly at the point where the optic nerve enters the eye. "For (says the latter author), on the first appearance of the yellowish or greenish spot, the retina on examination is found to be entirely deficient, or, in other words, to have degenerated into the malignant fungus. It is also found that the choroid membrane, while the fungus hæmatodes is in its incipient state, does not appear to have suffered any remarkable alteration in its texture, and that it is only at a more advanced period of the disease that this membrane becomes thickened, and separated from its connection with the sclerotica. The choroid membrane, even in the most advanced stage of the disorder, preserves, more than all others, its natural texture." (*On the Principal Diseases of the Eye*, p. 507, ed. 2.) Dr. Mackenzie has observed, that the sclerotica appears to suffer less than any other part of the eye, and that in every case where the disease affected the eyeball, "we were ignorant of its existence before either the optic nerve, or retina, was changed." Mr. Middlemore also declares his belief, that the disease begins either in the retina or optic nerve. (*On Diseases of the Eye*, vol. ii. p. 402.)

The lachrymal gland is sometimes absorbed; in other instances, projected from the orbit; but, according to Mr. Middlemore's experience, it does become affected with fungus hæmatodes. (*Vol. cit.* p. 407.)

In cases of fungus hæmatodes the sight of young subjects is generally destroyed before the attention of parents is excited to the distemper. Frequently, however, a blow, followed by ophthalmia, precedes the growth of the diseased mass. When no external violence has occurred, the first symptom is a trivial fulness of the vessels of the conjunctiva, the iris becoming, at the same time, extremely vascular, and altered in colour, and the pupil dilated and immoveable. There is seldom much complaint made of pain: but the child is sometimes observed to be languid and feverish. In adults, fungus hæmatodes of the eye generally comes on without any apparent cause, though sometimes in consequence of a blow. At first the tunica conjunctiva is slightly reddened, and vision indistinct. The redness and obscurity of sight increase slowly, and an agonising nocturnal headache is experienced; the eye bursts, and the humours are discharged.

The time of the greatest pain is at the period when the eyeball is greatly distended by the diseased mass, and previously to the rupture of the cornea. This is the time when convulsions are disposed to occur. (See *R. Middlemore, On Diseases of the Eye*, vol. ii. p. 395.)

With regard to the cure of fungus hæmatodes of the eye, the only chance of effecting this desirable object depends upon the early extirpation of the diseased organ. It must be acknowledged, however, that most of the operations in which the morbid eye has been removed, have hitherto proved unsuccessful, owing to a recurrence of the disease. The reason of such ill

success may be imputed to the optic nerve and other parts being almost always in a morbid state before an attempt is made to remove the eye. One case, however, described by Mr. Travers as having its seat in the cellular texture connecting the conjunctiva to the cornea, was operated upon, and no recurrence of the disease had occurred a twelvemonth afterwards. No other texture was affected more than the contiguity and extent of the disease explained. (*Synopsis*, &c. p. 413.) The most successful extirpation of an eye in an advanced stage of this disease, and perhaps almost the only satisfactory one at present on record, is that which was performed by Mr. Wishart, the cure remaining complete eighteen months after the operation. (See *Edin. Med. Journ.* vol. xix. p. 51.)

Donega operated in another case, as is alleged, with success. The disease had existed six weeks; and the patient was an infant, twenty months old. (See *Panizza, Sul Fungo Midollare dell' Occhio*. Pavia, 1826.) Some observations have been made by Mr. Lawrence on these cases, tending to raise a doubt of their having been examples of fungus hæmatodes. (*On Diseases of the Eye*, p. 623.) The operation has nearly always been found to fail when the disease is advanced so far that the posterior chamber is filled by the fungous mass. With the very few exceptions which there are to this statement, it may be correctly said that, as no internal medicines nor external applications afford the least hope of checking any form of the fungus hæmatodes, it is manifest that, when the distemper of the eye exceeds certain bounds, the miserable patient is placed beyond the reach of any effectual aid from surgery. In a case which I saw in April, 1821, in the London Eye Infirmary, the disease formed a mass as large as an orange, accompanied with enlarged lymphatic glands over the parotid. The patient was an infant. In this instance, Mr. Lawrence used, as a local application, the liquor opii sedativus, prepared by Battley, which was found to lessen considerably the child's sufferings.

Under the terms BRONCHOCELE, MAMMA, TESTICLE, and TUMOR, will be found descriptions of fungus hæmatodes, or medullary sarcoma, in organs not particularly noticed in the preceding article.

See *Dissertations on Inflammation*, by *J. Burns*, vol. ii. *Hey's Practical Obs. in Surgery*, ed. 3. *John Abernethy*, *Surgical Obs.* 8vo. Lond. 1804. *G. Freer*, on Aneurism, 1807. *Obs. on Fungus Hæmatodes, or Soft Cancer*, by *James Wardrop*; 8vo. Edin. 1809. This last publication is highly deserving of attention; the disease in different organs being well described, and its character discriminated from that of scirrhus cancer.

A case of this disease is related in vol. v. of the *Lond. Med. Journ.* It was the consequence of an attempt to cure a ganglion by means of a seton, and it proved fatal. *Abernethy's Surgical Obs.* 8vo. Lond. 1804. See also a case of diseased Testicle, accompanied with Disease of the Lungs and Brain, by *H. Earle*, in

Medico-Chirurg. Trans. vol. iii. p. 59, &c. in which vol. four other cases are recorded by *Mr. Lawrence*, p. 71, et seq. and one by *Mr. Langstaff*, p. 277; which last I remember to have visited in company with this gentleman and *Mr. Lawrence*, a short time before the patient died. FURUNCULUS (from *furo*, to rage.) A boil, so named from the violence of the heat and inflammation attending it. A peculiar inflammation, beginning, as Dupuytren believed, in one or more of the prolongations of the interareolar cellular tissue of the cutis.

A boil is a circumscribed, very prominent, hard, deep red, inflammatory swelling, which is exceedingly painful, and commonly terminates in slow and imperfect suppuration. The figure of the tumor is that of a cone, the base of which is considerably below the surface of the skin. Upon the most elevated point of the boil a small whitish speck presents itself, between the fourth and the eighth day. After the apex of the tumor has turned white, it softens, and then a very small aperture is formed in it, from which a little pus mixed with blood, is discharged, and within which a portion of dead cellular tissue, the core, may be perceived. By Dupuytren, and other French pathologists, the manner in which this is produced is explained as follows: a boil is only an inflammation of the prolongations of cellular tissue, which penetrate between the areolæ of the cutis, accompanied by the vessels and nerves, distributed to the surface of the skin. With this inflammation is combined that of the cutis itself, and consequently these cellulo-vascular and nervous prolongations suffer constriction, partly from their own enlargement, and partly from the increased narrowness of the openings through which they pass. Hence their nutrition is interrupted, and they are converted into a slough, called the core. (See *M. Solon*, in *Dict. de Méd. et de Chir. Pratiques*, art. *Furoncle*; also *Dupuytren*, in *Clin. Chir.* t. iv. p. 210.)

The complaint is not attended with fever, except when the tumor is larger than usual, situated on a sensible part, or when several boils occur at the same time in different places. In the last circumstance they often produce in children, and even in irritable adults, restlessness, loss of appetite, spasms, &c. When boils are situated in the perinæum, between the anus and the scrotum, there may be difficulty in making water. Sometimes, when placed on the nape of the neck, shoulder, or thigh, they excite inflammation of the lymphatic vessels and glands of the neck, armpit, or groin. (See *Rayer*, *Mal. de la Peau*, t. ii. p. 548.) They rarely exceed a pigeon's egg in size, and may originate on any part of the body, though it is most common for them to take place on the nates, the thighs, the armpit, the nape of the neck, the back, and in other regions where the skin is

thickest, and the prolongations of the areolar tissue most developed.

Young persons, and especially those of plethoric habits, are most subject to boils. The disease occurs with most frequency in the spring. (*Lassus, Pathologie Chir.* t. i. p. 16.) It is sometimes accompanied by a disordered state of the gastric organs. (*Nosographie Chir.* t. i. p. 124, edit. 2.) Frequently boils arise without any evident cause, and apparently in healthy constitutions. At other times they follow eruptive diseases and typhus. (*W. Gibson, Institutes, &c. of Surgery*, p. 48, vol. i.) In many cases several boils present themselves, either at once, or in succession, on various parts of the body.

The suppuration attending a boil is never perfect, and the matter which forms is frequently tinged with blood. The central portion of dead cellular tissue, or the *core*, is mostly detached about the tenth or twelfth day, leaving an open cylindrical cavity, extending from the apex to the base of the tumor. The pain now ceases; the skin contracts; the cavity becomes obliterated; and the cure is completed in about a fortnight. (See *Rayer, Mal. de la Peau*, t. ii. p. 547.)

The experiments of Dumeril and Bretonneau prove that a boil may sometimes be stopped by an early application of caustic; a plan, however, rarely tried.

In a very few cases, perhaps, it may be proper to try to resolve boils, by means of gentle evacuations, low diet, and cold applications. In the generality of instances, suppuration must be promoted by the use of emollient poultices. The tumor, when allowed to burst, generally does so at its apex. However, as the opening is long in forming, and too small to allow the sloughy cellular substance to be discharged, it is best, as soon as matter is known to exist in the tumor, to make a free opening with a lancet, and immediately afterwards to press out the matter and dead cellular tissue. This having been accomplished, healthy pus will be secreted, and the part will granulate and heal.

For the purpose of stimulating the cavity, and causing it to fill up, Professor Gibson, of Philadelphia, has sometimes employed a lotion of nitrate of silver.

Where there is reason to suppose the gastric

organs to be in a disordered state, an emetic should be given in the early part of the treatment, and afterwards small repeated doses of any of the mild purging salts.

When an indolent hardness continues after the inflammatory and suppurative state of boils has been removed, the part should be rubbed with camphorated mercurial ointment.

Besides the above *acute* boil, authors describe a *chronic* one, which frequently occurs in subjects who have suffered severely from the small-pox, measles, lues venerea, scrofula, and in constitutions injured by the use of mercury. The *chronic* boil is commonly situated upon the extremities, is of the same size as the acute one, has a hard base, is not attended with much pain, nor any considerable discoloration of the skin, until suppuration is far advanced, and the matter is seldom quite formed before the end of three or four weeks. Sometimes several boils of the chronic kind occur together, or follow one another in the same patient. The discharge is always thinner than good pus, and when the boil is large, and has been long in suppurating, a great deal of sloughy cellular tissue must be cast off before the sore will heal.

The principal thing requisite in the local treatment of all furunculous and carbuncular tumors is to make an early free opening into them, and to press out the matter and sloughs, employing emollient poultices, till all the mortified parts are detached and removed, and afterwards simple, or more or less stimulating dressings.

[Nélaton objects to incisions in the treatment of carbuncles and boils. He does not admit that the core is a portion of dead cellular tissue, but considers it a deposit or secretion resulting from an inflammatory action of a peculiar character, and compares it to the plastic membranous productions found in inflammations of serous membranes. For a more detailed account of M. Nélaton's views, see CARBUNCLE.]

G

[GALL BLADDER.—The surgeon may be called upon to puncture the gall-bladder in cases of obstruction of the biliary ducts. Thus Frerichs mentions the case of a lady whose gall-bladder reached downwards to an inch and a half below the crest of the ilium, and elevated the abdominal wall in the form of a pear-shaped tumor. Owing to the great tension and pain it occasioned it became necessary to puncture it, and from the presence of adhesions there was no danger in effecting this. About ten ounces of bile flowed out. The proper instrument for such an operation is a hydrocele trocar.]

H. Ansell.

GANGLION. (Γάγγλιον.) In surgery, an encysted tumor, formed in the course of a tendon, or its fibrous sheath. It is, as I have said, an

encysted, circumscribed swelling, commonly free from pain, causing no alteration in the colour of the skin, and formed upon tendons in different parts of the body, but most frequently upon the hand or wrist. A French gentleman consulted me, who had one upon the upper part of his foot, which created a considerable weakness in the motion of the ankle. A ganglion has been met with over the tendon of the trochlearis, and also that of the external head of the gastrocnemius. (*Aston Key, in Guy's Hospital Reports*, vol. i. p. 416, 417.) An example is recorded in which a ganglion, situated exactly over the arteria radialis and the arteria superficialis volæ, was at first supposed to be an aneurism. (See *Edin. Med. and Surg. Journ. for April*, 1821.)

Ganglions often possess considerable elasticity. They may occur unpreceded by any accident: but frequently are the consequence of bruises and violent sprains. When opened they are generally found to be filled with a viscid transparent fluid resembling white of egg, or rather jelly. As Mr. Aston Key has observed, the contents of a ganglionic tumour differ from those of a common bursa mucosa. The latter secretes a fluid like ordinary synovia; the ganglion most usually contains a substance like the outer layers of the crystalline lens, soft, viscid, and nearly solid. (See *Guy's Hospital Reports*, vol. i. p. 415.)

Different pathological views are entertained respecting the formation of ganglions. In France these tumors are regarded as dropsies or hydroceles of the sheaths of tendons. Most of them, it is observed, form over small compact joints, like those of the carpus and tarsus, possessing little motion, and covered by dense fibrous layers; or else, in the course of the sheaths of the tendons of the hand or foot. In these small arthrodial joints, and in the sheaths of tendons, the synovial membrane being covered by strong fibrous textures, cannot undergo any uniform distension by an accumulation of their secretion, which causes a protrusion of the synovial membrane at some interspace of the fibrous investment, which, however, extends over other parts of the internal cyst. It is also alleged that the ganglion has a communication with the interior of the fibrous sheath. (See *Bégin*, in *Dict. de Méd. et de Chir. Pratiques*, art. GANGLION.) Mr. Aston Key joins in representing ganglions as consisting of a double bag: the outer one tendinous and firm; the inner, like a synovial one, thin and secreting; but that, in most instances, the outer one cannot be separated from the inner. However, he differs from M. Bégin in regarding a ganglion as a new structure. (*Guy's Hospital Reports*, vol. i. p. 415.)

Stimulant applications sometimes succeed in curing ganglions, and, at one time, frictions with oleum origani, or with liniment of camphor, strengthened with tinct. canthar., were a common method. Of late years, friction with iodine liniments and the ointment of iodide of potassium, has also had extensive trials. I have often seen the tumors lessened by these means, but seldom cured; for, no sooner has the friction been discontinued, than the fluid in the cyst has accumulated again.

Compression is often employed. Persons with ganglions have been recommended to press upon them strongly with their thumb several times a day. After this has been repeated very often, the tumor has sometimes disappeared. Another method is to make pressure on ganglions by means of a piece of sheet-lead, bound upon the part with a bandage. In conjunction with this treatment, frictions with stimulating liniments or camphorated mercurial ointment are usually tried.

For the ganglion of the tendinous investment of the patella, a seton is occasionally employed by Mr. Key. "Blisters, stimulating plasters, and pressure with a bandage (he observes), are often resorted to with advantage. The more effectual plan of dispersing them altogether, is to puncture them with a lancet, to let out the contained fluid, and to employ firm pressure with a bandage and plaster. If this does not prove permanently successful, the seton becomes the most ready, the

most mild, and the most effective remedy." (*Op. cit.* vol. i. p. 417.)

Ganglions may be cured by pressure sufficient to rupture the cyst; and some authors have recommended putting the hand affected upon a table, and then striking the ganglion several times with the fist, the back of a book, or a mallet. The cyst of a recent ganglion may also be burst, by compressing it strongly with the thumbs, with or without the intervention of a piece of money; the fluid is effused into the adjacent cellular membrane; and, pressure being now employed, the opposite sides of the cavity become united by the adhesive inflammation, and the recurrence of the disease is prevented. On this principle, Sir Astley Cooper has often cured the disease.

For many years I have adopted the plan of curing ordinary ganglions by making a small puncture in them, discharging their contents, and then applying pressure. I have never seen any unpleasant effects follow this practice, and it is almost always successful. In 1825, Mr. Wm. Cumin, of Glasgow, published some cases and observations in favour of this method. He made the puncture with a cataract needle. (See *Edin. Med. Journ.* No. lxxxiv. p. 95.) I have usually drawn the skin a little towards one side, and then made a small opening in the ganglion with a lancet. In the treatment of ganglions situated on the back of the wrist, Mr. Aston Key also prefers a small puncture. For those which occupy the base of the palmar side of the fingers, he considers the puncture the only remedy; for the cyst cannot be ruptured, and blisters rarely answer. (See *Guy's Hospital Reports*, vol. i. p. 416.)

When ganglions become extremely inconvenient, either by obstructing the functions of a joint or causing pain, they should be carefully dissected out by first making a longitudinal incision in the skin covering them, then separating the cyst on every side from the contiguous parts, and, lastly, cutting every particle of it off the subjacent tendon or fascia.

The operation being accomplished, the skin is to be brought together with sticking plaster, and a compress placed over the situation of the tumor, with the view of healing the wound and the cavity by adhesion.

When the ganglion has burst, or is ulcerated, it is best to remove the diseased skin, together with the cyst; and of course the incision must be oval, or circular, as may seem most convenient. The grand object is not to allow any particle of the cyst to remain behind, as it would be very likely to throw out a fungus, and prevent a cure. In *Warner's Cases of Surgery* is an account of two considerable ganglions, which this gentleman, in imitation of Celsus and Paulus Ægineta, thought it right to extirpate. These had become adherent to the flexor tendons of the fingers. In the operation, he was obliged to cut the transverse ligament of the wrist; and the patients, who before could not shut their hands, nor close their fingers, perfectly regained the use of these parts. Mr. Gooch relates a case of the same kind, which had been occasioned by a violent bruise, three or four years before. The tumor reached from the wrist to the middle of the hand, and created a great deal of pain. Mr. Gooch extirpated it, and then restored the position of the hand, and free motion of the joint by the use of emollient applications, and

suitable pressure, made with a machine constructed for the purpose. (See BURSA MUCOSA.)

Other cases, confirming the safety of cutting out ganglions, are recorded in the London Medical Journal for 1787, p. 154; by *Eller*, in *Mém. de l'Acad. des Sciences de Berlin*, t. ii. ann. 1746; *Schmucker*, in *Chir. Wahrnehmungen*, b. i. p. 332; *Girard*, *Lupologie*. See *Warner's Cases in Surgery*. *Chirurgical Works of B. Gooch*, vol. ii. p. 376. *Richter*, *Anfangsgr. der Wundarzn.* b. i. Lassus, *Pathologie Chir.* t. i. p. 399. *Dict. des Science, Méd.* t. xvii. p. 311. *Cumin*, in *Edin. Med. and Surgical Journ.* No. 84. *C. Aston Key*, in *Guy's Hospital Reports*, vol. i. 8vo. Lond. 1836.

GANGRENE (from *γρᾶίνω*, to feed upon). So named for its eating away the flesh. Authors have generally distinguished mortification into two stages: the first, or incipient one, they name *gangrene*, which is attended with a sudden diminution of pain; a livid discoloration of the part, which, after being yellowish, becomes of a greenish hue; a detachment of the cuticle, under which a turbid fluid is effused; and lastly, on touching the part, a crepitus is perceptible, owing to the generation of air in the gangrenous parts.

When the part has become quite cold, black, fibrous, incapable of moving, and destitute of all feeling, circulation, and life, this is the second stage of mortification, termed *sphacelus*. Gangrene, however, is frequently used synonymously with the word mortification. (See MORTIFICATION, and HOSPITAL GANGRENE.)

GASTROCELE (from *γαστήρ*, the stomach, and *κῆλη*, a tumour). A hernia of the stomach.

GASTRORAPHIA, or **GASTRORAPHE** (from *γαστήρ*, the belly, and *ραφή*, a suture). A suture of the belly, or some of its contents.

Although the term *gastrophie*, in strictness of etymology, signifies the sewing up of any wound of the belly, yet Mr. S. Sharp informs us that, in his time, the word implied that the wound of the abdomen was complicated with another of the bowels.

The operation of sewing up a wound in the bowels, can only take place when they fall out of the abdomen, and the wound in them is visible. And, indeed, even in these circumstances, the employment of sutures is a practice, the propriety of which is questionable, as will be further considered in the article WOUNDS.

Gastrophie, or merely sewing up a wound of the parietes of the abdomen, is usually done with the common interrupted suture (see SUTURE), but occasionally with the quilled suture or with pins.

In from three to eight days, the sutures may generally be removed, and sticking plaster alone employed. (See WOUNDS OF THE ABDOMEN.)

M. Pibrac, in the third volume of the *Mém. de l'Acad. Royale de Chir.*, records several interesting cases, which fully prove that wounds of the belly readily unite by means of a suitable posture and a proper bandage, without the practice of gastrophie. These cases, however, are less decisive and convincing (if possible to be so) than the relations of the Cæsarean operation, the extensive wound of which has often been healed by simple means, after the failure of sutures.

Under certain circumstances, however, it may be essentially necessary to practise gastrophie. For instance, were a large wound to be made across the parietes of the abdomen, a suture might become

indispensably requisite to prevent the protrusion of the bowels. Yet even in this case, the sutures should be as few in number as possible. (See SUTURES.)

[Gastrophie has of late years been frequently employed after the operation of ovariotomy. The interrupted suture with silk or silver wire is preferred by most surgeons, but the quill and twisted sutures have also been used. In the present day adhesive plaster alone would not be depended upon, to unite wounds implicating the whole thickness of the abdominal wall.]

I shall conclude this article with a fact, perhaps more curious than instructive, related by M. Bordier, of Pondicherry, in the *Journal de Médecine*, vol. xxvi. p. 538. An Indian soldier, angry with his wife, killed her, and attempted to destroy himself by giving himself a wound with a broad kind of dagger in the abdomen, so as to cause a protrusion of the bowels. A doctor of the country, being sent for, dissected between the muscles and skin, and introduced a thin piece of lead, which kept up the bowels. The wound soon healed up, the lead having produced no inconvenience. The man was afterwards hanged, and M. Bordier, when the body was opened, assured himself more particularly of the fact.

GLAUCOMA (from *γλαυκός*, bluish green,) has been generally defined to be a greenish opacity of the vitreous humour, attended with the loss or a considerable impairment of sight. (*Weller, On Dis. of the Eye, transl. by Monteith*, vol. ii. p. 27.) Mr. Lawrence describes the colour as sea-green, clear green, muddy green, or yellowish green. (*On Dis. of the Eye*, vol. iii. p. 494.) As will be presently explained, however, the vitreous humour is not invariably implicated in some of the cases, perhaps incorrectly classed with glaucoma. Professor Beer considers the subjects of glaucoma, and the cataracta viridis, or glaucomatosa, together. He observes, that these diseases occur rather frequently, not only as true effects of inflammation of the eye, but sometimes quite unpreceded by this affection. Although glaucoma may continue for a long time as the only disorder, without the crystalline lens being changed in the slightest degree; yet Beer has never seen the case reversed, and the lens become altered as it does in glaucoma first, and the vitreous humour afterwards. In what this author describes as gouty ophthalmia, glaucoma is said to come on with the following symptoms: the iris is not observed to expand, but rather to become contracted; the pupil is not equally dilated, but extends more towards the canthi, the iris at length becoming scarcely perceptible towards each angle of the eye, especially the outer one, and the pupil of course assuming something of the appearance which is seen in the eye of a ruminating animal. In a case, however, which I once saw in the London Eye Infirmary, under Mr. Lawrence, it was particularly remarked that the diameter of the pupil was not greatest in the transverse direction; a circumstance which Beer's account would lead us to expect as constant. And it merits notice that, as the iris shrinks towards the margin of the cornea, its pupillary edge is inverted towards the lens, so that its smaller circle completely disappears. In this very dilated state of the pupil, a grey greenish opacity is perceived, seeming to be very deep, and arising from a real loss of transparency in the vitreous humour. At this period,

the lens evidently becomes opaque, acquiring a sea-green hue, and the cataracta viridis, or glaucomatosa, now swells and appears to project forwards into the anterior chamber. The pain then becomes more incessant and violent; the varicose affection of the eyeball seriously increases; and the eyesight, which began hourly to diminish from the moment when the pupil was first observed to be in any degree expanded and opaque, and the iris motionless, is now so entirely destroyed, that not the slightest perception of *external* light remains, though the patient may vainly congratulate himself on discerning luminous appearances produced within the eye itself, in the form of a fiery, shining circle, especially when the organ is gently pressed upon. An eye in this condition (says Beer) has really a look as if it were dead, the cornea being as flaccid and void of lustre as in a corpse. Finally, when these symptoms have attained their utmost pitch, an atrophy of the eyeball follows, and the painful sensations about the organ cease. In corpulent individuals, however, they still continue with greater violence. Sooner or later, the other eye is also attacked with arthritic iritis, or ophthalmia, or becomes affected with glaucoma, which is ushered in by violent and incessant headache. (Beer, *Lehre von den Augenkrankheiten*, b. i. p. 581, &c. 8vo. Wien, 1813.) According to this author, glaucoma and the green cataract are never the consequences of any description of ophthalmia, but what he terms *arthritic*. (b. ii. p. 255. Wien, 1817.) Mr. Lawrence inclines to Beer's opinion; for, he observes, that glaucoma appears to him to be a chronic form of arthritic inflammation of the internal tunics; and, he adds, that it certainly occurs more frequently in gouty persons than others. (*On Dis. of the Eye* ed. iii. p. 495.) I have stated that glaucoma is usually regarded as an opacity of the vitreous humour. The following, however, were the particulars observed by Dr. Mackenzie in the dissection of several glaucomatous eyes. 1. The lens of a yellow, amber, or reddish brown colour, especially towards its centre; its consistence firm, and its transparency perfect, or nearly so. In some cases, however, the reddish brown colour of the central part of the posterior lamellæ was so deep as considerably to impair its transparency. The part in question was also drier than natural. 2. The vitreous humour in a fluid state; perfectly pellucid, colourless, or slightly yellow: no trace of hyaloid membrane. 3. The choroid coat, and especially the portion of it in contact with the retina, of a light brown colour, with little or no appearance of pigmentum nigrum. 4. In the retina, no trace of limbus luteus, or foramen centrale.

[Dr. Mackenzie attributes the greenish appearance of the deep-seated parts of the eye in glaucoma, to the first of these changes, viz.: the amber or yellowish brown colour of the lens, and states that in some incipient cases this was the only change that could be detected on dissection. The glaucomatous lens, viewed in its natural situation, seems of a greenish, sometimes of a deep sea-green colour. Taken out of the eye, all greenness is gone, both in the eye deprived of its crystalline, and in the lens under examination. In glaucoma, then, the lens has become in a certain sense diplo-chromatic. The lens and the vitreous humour, which is also often yellowish in glaucoma, have the power of analysing the incident light, absorbing the violet, blue, and red rays, leaving the yellow and green

rays but little affected, so that they are dispersed; whence results the apparently green appearance of the humours. (*On Dis. of the Eye*, ed. iv. p. 897).

This author, however, thinks that in the later stages of the disease the lens may become opaque and cataractous, as well as glaucomatous, constituting the cataracta viridis or glaucomatosa of Beer.]

In some other cases which Mr. Middlemore had an opportunity of dissecting, the vitreous humour was of a yellow tinge, as remarked by Scarpa in his examinations; and the lens had undergone no other alteration than such as generally takes place in advanced life, being of a green, deep yellow or amber. The vitreous humour was not much increased in quantity. The choroid pigment was in a great measure absent; and the septa of the hyaloid membrane were absorbed. See *Middlemore on Dis. of the Eye*, vol. ii. p. 7.)

This gentleman describes two varieties of glaucoma: first, that which occurs in old age, and is productive of mere impairment of vision, without any material degree of pain, and, as he believes, without any inflammation; but in which the transparency of the vitreous humour is always diminished, and its colour altered, either to a yellowish or greenish tinge. Secondly, that variety which takes place from inflammation of the septa of the vitreous humour, which is marked by symptoms of a more or less severe character; is often attended with chronic inflammation of other deeply seated textures, and usually leads to the total destruction of vision. Hence, says Mr. Middlemore, the appearances of the membranes and humours will not always be the same.

In Mr. Lawrence's valuable treatise are collected the particulars of other dissections of glaucomatous eyes by Walther, Eble, and Rosas. In the eyes of a man examined by Walther, the lens and vitreous humour were in the normal state, and perfectly transparent. In the retinae were numerous black and partly reddish spots, roundish, and of various size. In a glaucomatous eye dissected by Eble, the covering of the uvea was reddish brown, instead of the usual dark pigment. The vessels of the choroid were varicose in several places; and the pigment, which was much lighter than natural, had disappeared in several places. The retina was extraordinarily soft, the lens was small, firm, and of amber colour, and its capsule was partially opaque. The whole vitreous humour had a yellowish tint; and there were scattered through it twenty or thirty points of a grey, brownish green, or sea-green colour. In another case, that of a man of 70, who had frequently experienced arthritic inflammation of the eyes, the vitreous humour was partially thickened, and firmer. The retina exhibited some varicose enlargements, and it was of a dark grey colour.

On this part of the subject, Mr. Lawrence offers the following judicious reflections: "From the preceding pathological facts, we may conclude that the vitreous humour is not originally and essentially the seat of glaucoma; we may perhaps draw the further inference that affections, in some respects different, are included under that term. When we consider the numerous gradations between the acute internal arthritic ophthalmia which destroys sight at once, and the imperfection of vision which comes on in glaucoma, properly so called; also that the difference of morbid changes may be expected, according to the stage of the

complaint; we shall not be surprised at finding that the results of examination are not always alike." (See *Lawrence, On Dis. of the Eye*, ed. 3. p. 497.)

In glaucoma, the pupil is green, or yellowish green: and if the eye be looked at laterally, no discoloration is seen. In cataract, the pupil is grey, or greyish white, and it has the same appearance in whatever direction it is viewed. In glaucoma, the loss of vision is not in direct proportion to the change of colour in the pupil. With an inconsiderable change, vision may be entirely destroyed, or seriously impaired; but in cataract there is a direct proportion between the degree of opacity and the injury to sight. In cataract, vision is best in a weak light; in glaucoma it is stronger in a powerful light, because, as the retina is less sensible, more light is required to make an impression on it. (*Lawrence, op. cit.* p. 498.)

Dr. Mackenzie was the first to apply the catoptrical test to the diagnosis of glaucoma from incipient cataract. The distinction between the appearances presented to the observer by the reflections from the flame of a candle in the two diseases, are mentioned in the article CATARACT.

Glaucoma, after it is conjoined with a varicose disease of the eyeball, is set down by Beer as incurable. According to Weller, when the vitreous humour first begins to be muddy, the disease may sometimes be checked. (*On Dis. of the Eye*, vol. ii. p. 29.)

Beer states that no treatment will avail in checking glaucoma, and preventing complete amaurosis. The prognosis is unquestionably most unpromising. I have seen many cases of glaucoma treated, but never with success. Mr. Lawrence holds out more encouragement than Beer, and recommends antiphlogistic treatment, as cupping; active purgatives; mercury, long continued, but not used so as to cause salivation; a regulated diet, and repose of the organ. (*On Dis. of the Eye*, p. 394.) Counter-irritation has also been found useful, and especially frictions with antimonial ointment between the shoulders. Arthritic inflammation of the eye is often greatly benefited by tonics, as precipitated carbonate of iron and sulphate of quinine. After depletion, one very experienced practitioner sanctions the trial of them in glaucoma. (See *Mackenzie, On Dis. of the Eye*, p. 899, ed. 4.) On the principle of there being a superabundance of dissolved vitreous humour, the same gentleman conceives that occasionally puncturing the sclerotica and choroid with a broad iris knife might prove serviceable. He also states that he has known glaucoma operated upon for cataract, and the removal of the amber-coloured lens followed by a considerable accession of vision. But as he had also known violent inflammation ensue, he does not venture to recommend this proceeding for general adoption. A grooved cataract needle, as recommended by Mr. Middlemore, seems to me the best instrument for puncturing the vitreous humour. Mr. Middlemore finds that no remedies will interrupt the progress of *senile glaucoma*, and he deems no treatment requisite, unless circumstances denote that the affection is rendered worse by the existence of chronic inflammation of the septa of the vitreous humour or neighbouring textures. If this be the case, he would employ mild purgatives, and, perhaps a little mercury, with permanent counter-irritation and the

avoidance of all exertion of the eye, particularly in artificial light, or on minute objects.

In the *acute* or *inflammatory* glaucoma, Mr. Middlemore is an advocate for antiphlogistic treatment, followed up by a seton or blister to the temple, or above the eyebrow. Sometimes he excites slight irritation on the skin of the temple with nitrate of silver. Occasionally he has punctured the vitreous humour with a very fine grooved needle. He advises this to be done whenever there is much local pain, evidently depending on the tension of the globe, "and particularly when vision is nearly destroyed, and the opposite organ is becoming similarly affected." In one or two cases, where the muddiness of the vitreous humour was evidently consequent on inflammation, Mr. Middlemore, after the subsidence of the latter affection, discharged the greater part of the turbid fluid with the needle, in the hope that the new secretion would be more transparent; and he states that he has practised this operation with the greatest advantage to the patient's vision. (See *R. Middlemore, op. cit.* vol. ii. p. 19—20) The dilatation of the pupil with belladonna sometimes improves vision, when this partly remains; but the benefit is merely temporary; and sometimes it causes an increased confusion of sight.

[The following remarks upon glaucoma are based upon an analysis of fifty-one cases which have been treated in the Royal London Ophthalmic Hospital, Moorfields, during 1857, 1858, and 1859.

We recognise two states of glaucoma, viz. the acute and chronic.

Acute glaucoma, nineteen cases.

A patient attacked by this disease presents the following symptoms, viz. severe pain in the eye attacked, and in the region of the fifth nerve of the corresponding side, diffuse redness of the subconjunctival tissue, sometimes accompanied with slight chemosis, and profuse watering occasionally. The eye feels hard, the cornea sometimes appears nebulous, the aqueous humour slightly turbid, the pupil irregularly dilated and fixed, its area greyish, or greenish turbid; vision is entirely lost, or reduced to faint perception of light. The turbid state of the media (humours of the eye) rarely admits of an ophthalmoscopic examination. All the cases where the fundus of the globe and the optic nerve could be seen, presented unmistakable signs of pressure at the optic nerve, generally with blood spots upon it or in the neighbouring retina. The fundus of the globe appears of a turbid red colour, and the optic nerve also, which has a grey red circle near its periphery; the retinal vessels while in the optic nerve are thin and hardly perceptible, but up to the retinal aperture are gorged with blood; the blood spots are sometimes confined to the optic nerve and the part of the retina nearest to it, in other cases the whole of the fundus is sprinkled with them.

The cases of acute glaucoma which came under my notice have been treated by Dr. Graefe's method, viz. by excision of a portion of iris, and with excellent results.

Such an acute attack, if left to itself, or treated in any other way, except by excision of part of the iris, may subside spontaneously, and vision become restored; but the attack will return, though perhaps in a less acute form, and finally lead to loss

of sight, and the eye will assume the characteristic appearance of chronic glaucoma.

In eyes which have been operated upon for this disease, the fundus, optic nerve, choroid, retina, &c. sometimes become visible the third day after the operation, and the retina is then frequently seen sprinkled with round and with large diffused blood spots; the latter are more frequent near the equator of the eye. The optic nerve is more red and well defined, the retinal vessels are of proportionate diameter throughout; sometimes the optic nerve has a more whitish, waxy appearance; in other cases the grey pink ring remains near its periphery: but in all cases the retinal vessels (in the nerve) lost their thin ill-defined shape and became gorged with blood. The round blood spots may remain for months, but the large diffused ones frequently disappear in a few weeks. The optic nerve may assume its normal pink appearance, or become more or less cupped. The youngest of the patients attacked by acute glaucoma, was a woman of 35 years of age, the oldest a man of 70. Occupation has no influence upon its occurrence. Thirteen of the patients were thin and pale, one stout and pale, and one in good health. Eleven of the fifteen had premonitory symptoms of two years' duration, while in others they were only noticed for a few weeks; they consisted in occasional increased hardness of the eye, pains in the forehead and temple, attacks of dimness of sight (especially during mental excitement), and in the perception of a halo (rainbow) round the candle. A few were troubled with flashes of light in the eye. Most of the cases became presbyopic, and had to use convex glasses. In four the attack came on without any premonitory symptoms, and in these the anterior chamber was nearly of the normal size. A rapid increase of presbyopia, of pains in the temple and forehead, and shorter intervals between the attacks of dimness, preceded the acute attack in eight cases. Three of the cases were attacked in both eyes simultaneously. We are in the habit of examining what the patient calls his sound eye, with a view of studying the prodroma of the disease. In most of the cases of acute and chronic glaucoma the other (sound) eye offers one or several of the symptoms mentioned above as premonitory. None of these eyes appeared to me to be ophthalmoscopically healthy; there was generally a marked loss of resistance to pressure at the optic nerve (*i.e.* the circulation was easily suspended); there were also increased redness of the nerve, with frequently the grey pink circle near its periphery, and some decrease of the amount of light observed in the vitreous space.

An acute attack not unfrequently occurs in those suffering from chronic glaucoma. The acute glaucoma has been observed in eyes which were blind from cerebral amaurosis; in cases where the iris and choroid had suffered from syphilis; in eyes where vision had been destroyed by chronic glaucoma; and where an advanced stage of atrophy of the optic nerve, choroid, &c. already existed.

Chronic glaucoma, thirty-two cases.

An eye affected with chronic glaucoma in its advanced stage (*i.e.* vision reduced to mere perception of light), generally presents the following symptoms: the globe is hard, the sclerotic is discoloured; enlarged, tortuous, subconjunctival vessels emerge into view in the ciliary region;

the cornea is flat, and has more or less lost its sensibility, as shown by Von Graefe; its epithelium not unfrequently peels off in flakes; the iris is discoloured and almost in contact with the cornea. The pupil is enlarged, irregular, and fixed; it appears greyish or greyish green. An ophthalmoscopic examination is possible almost in all cases, though the pupil may appear very hazy. The fundus appears red, and the optic nerve well defined and cupped. The retinal veins are gorged with blood up to the margin of the cup, where they either disappear entirely, or become thin and scarce while in the cup. Pulsation of the arteries in the cup exists either spontaneously or can be produced by gentle pressure on the eye. The ages of the thirty-two cases varied from 43 to 76; they were, with some exceptions, weakly, pale, thin persons, with feeble pulse: five had suffered from severe rheumatic attacks; three from erysipelas of the head shortly before the premonitory symptoms set in; others attributed the cause of the disease to mental anxiety. With two or three exceptions all the patients had been using convex glasses for reading. The time when the first symptoms of the disease appeared, varied from fifteen years to three months. They consisted of a halo round the candle, occasional mist before the eyes, increase of presbyopia, occasional pains in the temples; in several cases the sight was lost without any pain or inflammatory symptoms: others had inflammatory attacks and pain after the eye had been blind, and others shortly before it became blind. As the disease progresses tension of the eye gradually increases, the iris advances, the cornea becomes flat, the vessels which merge in the ciliary region enlarge, the pupil becomes irregular, then less moveable, and finally neither acts by itself nor in concert with the fellow-pupil; its area becomes greyish or greenish. In fifteen out of the thirty-two cases both eyes were attacked, and in three to an equal extent; three of the cases had repeated slight attacks of inflammation (sub-acute glaucoma), and several had chronic glaucoma in one eye, while the sound eye was seized by an acute attack.

Changes of the retina and optic nerve in glaucoma.

Vision. In the beginning of acute and chronic glaucoma we observe a weakness of sight, which obliges the patient to wear convex glasses for near small objects, and an inability to recognise distant small objects; this is followed by occasional attacks of dimness: the patients, for instance, suddenly lose sight of an object, or it appears indistinct, and as if seen through a grey mist; they then notice a halo of different colours round the candle; at a later period they complain of not being able to see so many objects round them at once as formerly, *i.e.* their field of vision becomes contracted. The attacks of pain generally appear at this period. The upper and lower parts of the retina lose, in most cases, their sensibility sooner than the outer and inner. The loss of vision advanced in a few cases from the temple towards the nose, without meeting with a misty portion intervening between the blind and sound part. The field of vision has often in an advanced stage somewhat the shape of a slit. It was frequently observed that when vision was reduced to perception of shadows, the inner portions of the retina retained their sensibility the longest. Flashes of light in the dark and with the eyes closed, were observed in one case, which, however,

was not a pure case of glaucoma. A patient may lose the sight of one eye without being aware of it. Other cases have occurred where a considerable loss of blood hastened the progress of glaucoma. Sudden loss of vision in slightly glaucomatous eyes, with or without pain, has occurred after stooping, during mental excitement, and during several other incidents which disturbed the circulation. Vision may return and then become gradually lost, or the eye may remain blind.

As for Von Graefe's operation it may be said that the more the turbid state of the media contribute to the impairment of vision, the better is the prognosis of the case; and also that those patients who were operated upon in due time, have not only retained the vision they had before the operation; but sight has, in the great majority been considerably improved.

Retina. Ophthalmoscopic examination.

A satisfactory idea of the state of this membrane cannot be formed in most cases of acute, and in some of chronic glaucoma, on account of the turbid state of the media. In all cases of chronic glaucoma we find, if the media are transparent, a slight loss of transparency of the retina; in advanced cases it appears hazy and greyish; the result of this state is that a smaller amount of light is obtained in the vitreous space than is usual, because the transparency of the retina is impaired by the glaucomatous changes in it, and thus intercepts the light. In all cases of acute and chronic glaucoma, which were complicated with a turbid state of the media, ecchymoses upon, in, and beneath the retina were observed, and a few fresh or old ecchymoses were seen in cases of chronic glaucoma with transparent media. Those which are in the substance of the retina are generally small, round, and well-defined; they remain persistent for two to three months, turn brown, and gradually disappear: those beneath the retina are flat, large and generally numerous; they disappear in from two to six weeks, leaving behind an irregular distribution of the pigment granules of the hexagonal cells; they impair vision much less than those in the substance of the retina, and are most numerous beneath the middle and anterior portions of that membrane. Those effusions of blood which perforate the retina towards the vitreous humour appear as small red clouds suspended in front of the retina; they are generally accompanied by grey opaque portions of the vitreous humour. Ecchymoses at the yellow spot, or optic nerve, are more dangerous to vision than those which occur around it. The appearance of these ecchymoses, I believe, coincides with the inflammatory attacks of glaucoma.

Retinal vessels. The retinal vessels in the fellow eye to the one attacked by acute glaucoma were, with one exception, large, numerous, gorged with blood, and unequally dilated. On the diseased side in all the cases of chronic glaucoma there was a decrease in the number of the arteries, and the veins appeared unequally dilated. The retina which carried the smaller number of blood-vessels was the most diseased; in some of the glaucomatous eyes which had been blind for years there were only one or two thin vessels traceable in the retina. After Von Graefe's operation, an increase in the diameter and number of the vessels in less advanced cases of chronic glaucoma and a return to the normal straight course was observed. The vessels of the retina were,

in some of the cases of acute glaucoma, numerous, tortuous, and gorged with blood; in others they were thin and few in number. The retinal vessels could not be traced to many of the ecchymoses. The optic nerve and the retinal vessels presented signs of intra-ocular pressure in all cases of acute and chronic glaucoma. These are

1. A facility of interrupting the circulation in the optic nerve by slight pressure upon the eye.

2. A spontaneous pulse in the arteries extending from the entrance of the artery to the point where it passes into the retina. This was in some accompanied by a movement of the veins, synchronous with it.

3. Decrease of all the vessels while in the optic nerve.

4. A change of colour of the optic nerve.

5. A cupping of the optic nerve in chronic and (after the inflammatory attack has passed by) in most of the acute cases of glaucoma, with a lateral displacement of the vessels, proportionate to the depth and the sharpness of the margin of the cup.

The following remarks regarding the state of the optic nerve and of the retinal vessels in it have been taken from the analysis of the above fifty-one cases:—

The changes observed in the sound eye (the fellow eye suffering from *chronic* glaucoma) were:

A. A decrease of vessels, chiefly of arteries.

B. An optic nerve in some cases of a pale pink; in others of a pale waxy appearance; in many cases with a greyish pink circle near its periphery, and a diminished resistance to pressure; in several cases with a tendency to an arterial pulse.

The changes observed in the sound eye (the fellow eye suffering from acute glaucoma) were: an optic nerve of a pale pink colour and rather small in size, the retinal vessels in it being thin and showing a marked loss of resistance to pressure.

Changes in the eye suffering from chronic glaucoma: A cupped optic nerve, with irregularities in the size and course of the retinal vessels. The cup or excavation in the optic nerve is slight at first, and frequently confined to a part of the nerve only, but may comprise its whole surface. It becomes gradually deeper, and in advanced cases reaches to the opaque portion of the optic nerve; in these cases the whole of the optic nerve fibres, from the retinal to the scleral aperture, have been destroyed; the retinal vessels are displaced sideways and pressed against the walls and the margin of the cup; the latter is formed by the scleral and choroidal aperture; the full retinal veins arrive at the edge of the cup, then wind round it, and reappear thin in the cup, or disappear after having passed the edge. The cupped optic nerve has, in chronic glaucoma, a grey white, or bluish grey appearance, which may turn red by effusions of blood; the vessels in a deep cup are thin, and pulsation of the arteries is rarely observed. The arterial pulse is frequently met with in the early stage of cupping of the nerve, and in eyes which suffer from slight inflammatory (glaucomatous) attacks. The optic nerve in less advanced cases assumes, after Von Graefe's operation, a waxy white appearance, the vessels become more numerous and can be traced over the margin of the cup.

The loss of vision is attributed to the destruction of the optic nerve fibres, these are pressed against the scleral and choroidal aperture: it has several times been noticed where the cup was confined to

one side of the nerve, that the retina of that side was paralysed. The cup is completed most rapidly when an acute attack occurs in a chronic glaucomatous eye, and it is formed secondarily in eyes which have suffered from acute attacks of glaucoma.

In the eye attacked by acute glaucoma, in one case the optic nerve appeared flat and full and the vessels thin; in two other cases the vessels were thick and tortuous and the optic nerve small and red; and in five cases was the optic nerve deep red, with a grey circle near its periphery, and the vessels were thin and hardly perceptible while in the nerve. The red colour of the nerve is due to imbibition of blood and to small hæmorrhages from vessels into the nerve. The nerve after Von Graefe's operation, remains red for a few days and then assumes a greyish-white colour, which, in the course of a year, in three cases, was followed by a moderately cupped bluish-grey optic nerve; the vessels in the retina and in the cup being equally large.

Pathology.—Dissection of eleven eyes which suffered from chronic glaucomatous changes. The eyes had no perception of light. The tension of the globes was lessened after excision. The consistence of the vitreous was greater (harder) than normal in eight, and somewhat viscid in one case. It had a yellowish tinge in all cases. It was replaced by yellowish fluid in an eye which was staphylomatous, and in another, where circumscribed effusions of blood had occurred, between sclera and choroid, thus displacing the latter with the retina. The fluid state did not extend beyond the displaced or staphylomatous portions. The whole of the vitreous had escaped in two cases in which bleeding had occurred between sclera and choroid, the latter having been displaced.

The choroid appeared very rotten, and was, in a few cases, gorged with blood, its pigment appeared normal round the optic nerve, but had in many places disappeared from the equator of the eye to the ora serrata; there it was thinned and atrophied; we may say that the choroid was the most atrophied where the retina was most changed, *i. e.* between the equator of the eye and the ora serrata. The hexagonal cells had, in most cases, their normal shape round the optic nerve; further on they became rounded off, and had entirely disappeared from the staphylomatous choroid and from its anterior portions; their granules appeared smaller, they had lost their lustre; the changes of the hexagonal cells were proportionate to those of Jacob's membrane (rods and bulbs).

The retina.—In most cases it appeared transparent to the naked eye, but hazy and pigment-sprinkled when examined microscopically; its tissue, was very rotten and more so from the equator forwards; it was in apposition with the choroid. No yellow spot was perceptible in two cases.

We shall treat of its constituents separately.

The rods and bulbs.—They were present round the optic nerve in all cases; but appeared large, swollen, and had lost their distinctness of outline; in many places they were greyish and sprinkled with minute grey granules. The swelling, indistinctness and greyish colour increased towards the equator; and no rods were found at most places near the ora serrata; there the outer surface of the retina had an uneven, greyish, translucent, amorphous appearance.

The radial fibres (continuation of some of the rods).—Those in the retina round the optic nerve were thin and ill-defined; those further on appeared still thinner; many had shrivelled away; others were hardly perceptible, especially those beyond the equator of the eye. I could only find them extend up to the inner membrana limitans in one eye. This change of the radial fibres gave the nerve cells the appearance of being heaped together indiscriminately; they had lost their regular arrangement into piles.

The nerve cells.—They could easily be distinguished from healthy ones by their slight loss of transparency; they resembled, in some instances, agglomerations of large fat globules, by their resistance to chromic acid (they did not become granular), and by their appearing swollen. The thickness of the layer of nerve cells had decreased round the optic nerve; it became thinner further on, and hardly any nerve cells were perceptible near the ora serrata. The layer of nerve cells which is level with the ganglion cells and with the blood-vessels, had in all cases been reduced to a finely granular hazy mass, which was sprinkled with grey and with brownish patches and in most cases with fresh blood spots, only in one instance could I see some ganglion cells.

The vessels.—A glaucomatous retina is remarkable for the great increase of capillaries; this vascularity is greatest in the thicker parts of the retina, but is still very considerable near the ora serrata, so that at that part the capillaries and an amorphous, grey, translucent, rotten membrane are the only remnants of the retina.

The arteries are few and thin.

The veins are varicose; an interruption of the inner coat of the veins, with a dilatation of this weaker portion of their walls, has been noticed in several cases.

The blood effusions (round blood spots), which are frequently observed in the retina round the optic nerve and near the equator, appear to have come from the veins and generally from their lower and lateral part, the blood spreading among the nerve cells or perforating the retina and displacing the rods. Sections of the vessels show that they are flattened in different directions. The capillaries form an exceedingly dense network of angular and arched canals, which, in many instances, are filled by yellowish serum; in others by serum and by pale swollen blood corpuscles; in others they are empty. All the capillaries are large and varicose; many are aneurismatic (the latter fact was first noticed by Mr. W. Hulke), especially those in the portions of the retina near the ora serrata. The aneurismata are empty in most cases; in a few they were filled with a brownish, yellowish or black amorphous substance. The retina in one case was sprinkled with large transparent cells, some of which were near blood-vessels; to many of these no blood-vessels could be traced: either the aneurismatic pouches had been left and the adjoining vessel destroyed, or these large cells were some new formation; they resembled the aneurismatic dilatations in their disappearing or shrivelling up on the addition of acetic acid. In other places the capillaries appeared to have been ruptured; and their contents, escaping among the nerve cells, to have caused the brownish patchy appearance of that layer.

The optic nerve fibres.—Only in a few cases, and

then only round the optic nerve, was I able to trace optic nerve fibres. The hyaloid surface of the retina was sprinkled with minute black pigment granules, many of which had a linear arrangement.

The optic nerve (where it passes into the eye).

The transparent portion of the optic nerve fibres was found destroyed in all cases; the cup thus formed in the optic nerve was filled by yellowish fluid, by an amorphous greyish mass, and in several cases, by blood. The sides of the cup were formed by the retinal, choroidal, and by part of the scleral aperture, the margin of the latter projected into the cup; the vessels were pressed upon the scleral margin. The fibrous tissue which formed the bottom of the cup was considerably thickened in several cases; in others the optic nerve (beyond the cup) appeared healthy, except a great quantity of pigment molecules, which were deposited into the fibrous tissue which surrounds the nerve fibres.

According to Mr. Dixon, "patients affected with glaucoma are almost invariably beyond the middle period of life; perhaps between fifty and sixty is the most common age for the occurrence of the disease. It usually affects both eyes. The globe, instead of having that slight degree of elasticity which it possesses in health, is peculiarly hard, giving to the finger almost the sensation of a stone.

"The sclerotic, which is often marked with faint dusky patches, is traversed by several large, tortuous, purple veins, emerging abruptly close to the margin of the cornea. Sometimes there is, in addition, a faintly marked, vascular zone; the cornea, although it may be sufficiently transparent to allow of the iris and lens being well seen, presents a peculiar unevenness of its epithelial surface; so that the lines of the window frame, instead of being distinctly and sharply depicted on it, appear broken, wavy, and irregular, and the light itself dull, as if reflected from a steamy glass.

"Sometimes the cornea is decidedly hazy throughout; and occasionally the epithelium is found vesicated in small patches, closely resembling minute drops of water which have run together on a dewy window-pane.

"If a good view of the iris and lens can be obtained, the former is found in close approximation to the cornea, equally dilated all around to a mere ring; or else the pupil is irregularly oval and quite fixed.

"It is commonly stated that the pupil in glaucoma is always transversely oval. This form, although very often seen, is by no means constant. The fibrous appearance of the iris is lost, and its colour, either in parts or throughout, is changed to a peculiar slaty tint. Sometimes the veins of the iris are sufficiently enlarged to be distinctly visible to the naked eye.

"The lens advances so as almost to touch the hinder surface of the cornea; it is opaque, sometimes rather milky looking, and indistinctly striated. Its threefold division is often very well marked, as if, by undergoing maceration in water, it had swollen up, and were about to burst its capsule. The colour of the lens varies much. It may be greyish or greenish drab, dirty yellow, or dull orange; and marked with opaque earthy patches or streaks.

"Vision of objects is wholly extinct; usually there is not even perception of light.

"I have said that the morbid appearances enumerated may be produced in two different ways. They may have been the slow result of disease going on, with intervals of apparent quiescence, for months or even years; or sight may have become extinct after a few hours of agony, and all the inflammatory changes in the tissues of the eye (except the opacity of the lens) be apparently completed within a few days.

"The chronic form begins very insidiously, and is probably set down as 'incipient amaurosis.' The patient complains of dimness of sight, and sometimes—by no means invariably—sees bright flashes or colours passing before him. Dull pain in the eye or in the head may, or may not, be present. In the former case, a faint vascular zone in the sclerotic often attends the onset of the pain. The iris gradually loses its briskness of movement, and the pupil becomes enlarged; not uniformly, but so as to assume an irregular instead of a circular form. It is sometimes transversely oval; but this shape is by no means so frequent as some writers have asserted.

"This state of things may go on for several months, without any very acute inflammation showing itself. Chronic iritis may then set in, the veins of the iris becoming visible, and the pupillary margin adhering to the capsule at one or two points. The sclerotic zone, in that case, would, of course, be developed. By this time vision may be lost, or restricted to the recognition of large, well-lighted objects. Then opacity of the lens begins slowly to show itself; or, perhaps, the cornea first becomes hazy, and its epithelium uneven, so that the increasing cataract is scarcely perceived. Gradually the iris and lens advance towards the cornea. The large, dark purple veins have by this time shown themselves on the surface of the sclerotic; and not until the end of many months, or even of a year or two, from the first failure of sight, does blindness become complete.

"The sequence of morbid changes seems to be as follows:—First, in the retina and choroid, going on, perhaps, to serous effusion between these coats, which causes the bulging forwards of the lens and iris, by pressing from behind upon the vitreous body; then congestion and inflammation of the iris and cornea; and, last of all, opacity of the lens, as a consequence of its deranged nutrition.

"As regards the treatment of the chronic form, it is quite impossible to lay down any rules which shall apply to all cases, it must be based upon a careful study of the patient's general health, and an avoidance of whatever may seem to have destroyed the due balance of the circulating forces. As a general principle it may be affirmed that the subjects of these insidious and dangerous changes in the eye are feeble and depressible, and therefore bleeding and salivation are most injurious. But, except in the very earliest stage of the disease, which is, unfortunately, very difficult to detect—the most careful treatment will often prove of little avail. In the acute form of glaucoma the sclerotic is slightly reddened, the veins emerging at the edge of the cornea are usually enlarged; the pupils dilated, oval and quite fixed; no decided opacity of the lens exists, but an ill-defined haziness of the pupillary space. The iris has a mottled, slaty tint and a more fibrous appearance, is bulged

forward and almost touches the cornea ; the cornea looks slightly dull, as if minutely granular ; the globe is stonehard and tender when pressed upon." (*Dixon, Diseases of the Eye*, p. 224, 1855.)

A surgical treatment of the acute and chronic form of glaucoma has been introduced by Professor V. Graefe, of Berlin ; the leading idea of the operation consists in relieving the intra-ocular pressure, and the operation essentially consists in introducing a cataract knife through the semi-transparent part of the sclerotic, close to the corneal edge into the anterior chamber, and making an incision from one-quarter to one-sixth of an inch long ; when the knife is withdrawn the aqueous humour and the iris follow it ; the prolapsing iris is drawn out at one corner of the section and the drawn-out portion snipped off with scissors, so that from one-quarter to one-third of it is removed ; it is supposed that by this means the vitreous and aqueous chambers are thrown into one, that the remainder of the iris atrophies, and that the tension of the globe being diminished, the absorption of the fluid effused in the deeper tissues of the eye, is encouraged ; the retinal vessels admitting more blood, small blood effusions are more frequent on the retina. Mr. Bowman introduces the knife at the upper edge of the cornea, thus allowing the upper lid to cover part of the very large pupillary opening.

The prognosis of chronic glaucoma depends upon the stage in which the eye affected is operated upon ; when *blind* for some time it is not expected to regain sight, and the operation is performed only to relieve pain and tension. A chronic glaucomatous eye, with mere perception of light, is *rarely* improved by the operation ; but generally the pain and the progress towards blindness are arrested. An eye with subacute glaucoma, and still more one suffering under an acute glaucomatous attack, offers the best prospects of success for the operation, especially if the attack has occurred very recently, and if the turbid state of the media contributes much to the loss of vision.

Of seventy-eight cases operated upon, six were cases of chronic glaucoma without perception of light ; one of them had both eyes operated on, two the right, and three the left eye only. Fifty-three more were cases of chronic and subacute glaucoma, with different degrees of impaired vision ; of these, nineteen had both eyes operated on, sixteen the left, and eighteen the right eye only. Nineteen were cases of acute glaucoma, eight of which had both eyes operated on, five the left, and six the right eye only.

Of the seven chronic glaucomatous blind eyes operated upon for the relief of pain and tension one requires mention. In this instance the lens capsule was touched, and hard portions of lens of a transparent yellowish appearance presented in the section ; the eye was at once closed, and pressure with a piece of cotton-wool applied ; no further escape of the contents of the eye followed, and the wound healed well, though the patient had a severe attack of what appeared to be catarrhal ophthalmia, with pains for three days.

Of the seventy-two eyes with chronic or subacute glaucoma operated on, with a view of restoring vision as well as of relieving pain and tension, bleeding from the iris into the anterior chamber occurred in twelve cases ; the blood escaped in

some cases from the ciliary attachment of the iris, in others from near the pupillary edge, and in some it was seen oozing from the free surface of the iris. The bleeding came on either during the operation or not unfrequently after the speculum had been removed. In one case it began a quarter of an hour after the operation, and in another the day following ; in the latter case it was followed by suppuration of the globe. The blood as it oozes out should be removed at once, otherwise it may clot, assume the shape of the anterior chamber, and is difficult to remove. The end of the scoop is generally placed in the corneal wound, and pressure with some other instrument is made upon the cornea from below towards the wound ; or simply pressure is made on the cornea with the scoop. It appears to be less safe to pass the scoop quite into the anterior chamber and thus to remove the blood. A counter puncture has been made in one case to allow the blood to escape. It takes, if allowed to remain, from three to nine days to become absorbed. The subacute form of glaucoma appears to be most liable to bleeding after the operation.

The lens in seven cases became opaque, without any fragments escaping : most of these cases had been operated upon with the lance-shaped knife.

Hard portions of transparent lens, where its capsule had been wounded, escaped in three cases ; the remainder of the lens became opaque in two of them : pressure to avoid further escape of lens or vitreous was applied. In the third case remaining fragments of the lens appear to have escaped *some time after* the operation, a clear pupil with improved vision being found the third day after it. There had been much pain in the eye for some time.

In one case the lens in its capsule presented in the section, and six hours after the operation was found with about a third of the vitreous humour (of abnormal consistence) at the side of the patient ; the pain, which had been severe, subsided after this had happened. Some lenticular fragments escaped also in another case in which the lens had not been touched ; some vitreous followed while removing the remainder of the lens with the scoop, but the application of pressure stopped any further escape that might have happened, and no pain followed.

The opaque lens of several of the above cases was extracted with a favourable result.

The section was, in some of the first cases operated upon, kept open by portions of iris which were left there, to allow the fluid which might accumulate in the anterior chamber during the first days after the operations to drain off.

A gaping of the section, with accidents similar to those accompanying an irritable prolapse of the iris after extraction, was in two cases caused by fluid vitreous, which distended the wound. It was gradually coated over with lymph and flattened down ; the lens remained transparent in both cases.

One case presented all the fatal accidents of the operation—first some difficulty in seizing the iris, then escape of some vitreous, then of the lens, then of a large portion of vitreous with the hyaloid fossa attached to it, then of the remainder of the vitreous, followed by about half an ounce of blood. Slight pressure was applied ; no pain followed.

Twenty-seven eyes attacked by acute glaucoma were operated upon. Three of them were fol-

lowed by bleeding from the iris, which appeared to stop after the small iris vessels were emptied. In one case the lens was wounded, it escaped with some of the vitreous, and a troublesome *iritis* with lymph formation followed.

Sixteen out of a hundred and seven eyes may be said to have been injured by the operation; that is to say, so many patients who would have lost vision if no operation had been done, went through a certain amount of pain and anxiety with a chance of having sight restored. It may be said that in about eighty cases the operation has had a good, and, so far, a lasting result.

For exact details the reader is referred to the tables which have been published in the Ophthalmic Hospital reports. The results for vision, later than those tabulated, are equally satisfactory: stationary in nearly all cases as regards the power of distinguishing small objects, and greatly improved as regards the recovery of sensibility of the more peripheral parts of the retina in many others.

Mr. Hancock (in No. 12 of the Ophthalmic Hospital Reports) recommends the division of the ciliary muscle in glaucoma. He states that "the ciliary muscle is either, as in the acute or earlier period of the disease, thrown into undue action, or, as in the advanced stages of the same complaint, is converted into a state of mere atrophy and is thus deprived of its elasticity, and that, from the peculiar arrangement of the vessels of the choroid with reference to this muscle, the circulation through these vessels is impeded." One object of the operation is "the improvement of the blood-vessels by removing constriction, and so relieving the circulation through them, with the view of either entirely arresting, or at all events of diminishing, the abnormal secreting action."

"The operation, which is very simple and by no means painful, is performed in the following manner: A Beer's cataract knife is introduced at the outer and lower margin of the cornea where it joins the sclerótica. The point of the knife is pushed obliquely backwards and downwards, until the fibres of the sclerótica are divided obliquely for rather more than one-eighth of an inch; by this incision the ciliary muscle is divided, whilst if there be any fluid accumulated it flows by the side of the knife. In performing the operation care should be taken not to allow the incision to extend at all into the transparent cornea, as when this takes place the iris is apt to protrude through the cut, and the pupil is consequently deformed by being drawn in that direction, &c."

The writer thinks it necessary to remark that he has met with several cases of glaucoma at the Eye Infirmary, Moorfields, which had thus been operated on by Mr. Hancock, and where a fresh glaucomatous attack made Von Graefe's operation of iridectomy necessary.

For a full account of the nature and treatment of glaucoma see *Archiv für Ophthalmologie* (edited by Von Graefe, Donders and Arlt). Bd. iii. Abthl. ii. Berlin, 1857,—and Dr. Stelmag von Carion, *Die Ophthalmologie*, &c. 1857.]

GLEET. By the term *gleet* is commonly understood a continued running, or discharge from the urethra, after the inflammatory symptoms of a clap have for some time ceased, unattended with pain or scalding in making water, &c. Mr. Hunter remarks that it differs from a gonorrhœa in being uninfected, and in the discharge consisting of globular bodies, contained in a slimy mucus, instead of serum. He says that a gleet seems to take its rise from a habit of action which the parts have contracted. The disease, however, sometimes stops of itself, even after every method of treatment has been ineffectually tried. This probably depends upon accidental changes in the constitution, and not at all upon the nature of the disease itself. Mr. Hunter had a suspicion that some gleets were connected with scrofula. Certain it is, the sea-bath cures more gleets than the common cold bath, or any other mode of bathing; and a cure may sometimes, but not always, be accomplished by an injection of diluted sea-water.

[The opinion of most surgeons of the present day is that a gleety discharge following a gonorrhœa is not lightly to be pronounced free from infecting properties. Very slight additional irritation, such as intercourse with the opposite sex would produce, may convert the colourless discharge of gleet into a purulent fluid, which will cause all the symptoms of gonorrhœa in a female.]

Gleets are often attended with a relaxed constitution. They also sometimes arise from other affections of the urethra, besides gonorrhœa. A stricture is almost always accompanied with a gleet; and so sometimes is disease of the prostate gland.

It is remarked by Mr. Hunter that if a gleet does not arise from any evident cause and cannot be supposed to be a return of a former gleet, in consequence of a gonorrhœa, either a stricture or diseased prostate gland is to be suspected; an inquiry should be made whether the stream of urine is smaller than common, whether there is any difficulty in voiding it, and whether the calls to make it are frequent. If there should be such symptoms, a bougie rather under the common size should be introduced; and, if it passes into the bladder with tolerable ease, and the patient is nearly fifty, or upwards, the disease is probably in the prostate gland, which should *next be examined*. (See URETHRA, *Strictures of*; and PROSTATE GLAND.)

Balsams, turpentine, and the tinctura cantharidis, given internally, are of service, especially in slight cases; and when they are useful, they prove so almost immediately. Hence, if they had neither lessened nor removed the gleet in five or six days, Mr. Hunter never continued them longer. The same observation applies to cubebs, so celebrated as a remedy for gonorrhœa and gleet, and the common dose of which is ʒij. in any convenient fluid three times a day. As the discharge, when removed, is apt to recur, such medicines should be continued for some time after the symptoms have disappeared.

When the whole constitution is weak, the cold

bath, sea-bath, bark and steel medicines may be given.

With regard to local applications, the astringents commonly used are lotions of sulphate of zinc, alum, or acetate of lead.

Stimulating applications consist either of injections, or bougies. Violent exercise may be considered as having the same effect. Such applications should never be used till the other methods have been fully tried and found unsuccessful. They at first increase the discharge, and, on this account, are sometimes abandoned too early. Two grains of the bichloride of mercury, dissolved in eight ounces of distilled water, make a very good stimulating injection. In irritable habits such an application may do great harm, and therefore, if possible, the capability of the parts to bear its employment should first be made out.

Bougies sometimes act violently, but Mr. Hunter thought them more efficacious than injections. A simple unmedicated one is generally sufficient, and must be used a month or six weeks before the cure can be depended upon. Bougies, medicated with camphor or turpentine, were formerly employed for the cure of gleet; they did not require so long a trial as common bougies: at present, I believe, they are not used by any surgeon of eminence. Whatever bougies are employed should be under a common size.

Mr. Hunter knew a gleet disappear on the breaking out of two chancres on the glans. Gleet has also been cured by a blister on the under side of the urethra, and by electricity.

In every plan of treatment, rest or quietness is generally of great consequence; but, after the failure of the usual modes, riding on horseback will sometimes immediately effect a cure.

Regularity and moderation in diet are to be observed.

Intercourse with women often causes a return or increase of gleet; and in such cases it gives suspicion of a fresh infection; but the difference between this and a fresh infection is, that here the return is almost immediately after the connexion.

Gleets in women are cured nearly in the same manner as those of men. Turpentine and balsams, however, have no specific effect on the vagina; and the astringent and stimulating injections used should be stronger than those intended for male patients.

[The mucous membrane of the urethra, like that of other parts of the body, in certain individuals, is very susceptible of irritation and readily secretes a larger quantity of mucus than usual on the slightest additional irritation; pus globules also are frequently added, so as to produce a mucopurulent secretion. Many gleets depend upon this constitutional peculiarity, and hence the difficulty experienced in their successful treatment.

The surgeon, therefore, must not fail to combine constitutional remedies with his local treatment, and these will vary in each individual case according to the state of the system and of the disturbance of the general health.

When the gleet is kept up by some diseased state of the urethra itself, or of the prostate gland, independent of any peculiarity of constitution, the case is more easy of cure. The appropriate remedies for stricture, for prostatic diseases, for enlarged lacunæ, for valvular folds,

for preternatural sensibility of particular portions of the urethra, must be had recourse to.

The instruments used by French surgeons for exploring the urethra—the *bougie à boule*, the *bougie à nœud*—may be of great service in detecting the existence and the locality of enlarged lacunæ, of valvular folds, or of increased sensibility.

Nelaton recommends valvular folds to be destroyed by a bougie used with force, or by a cutting instrument introduced through a canula: for the increased sensibility of portions of the urethra he advises injections by means of a catheter having an orifice at its extremity, and passed down to the sensitive point so as to insure the application of the injection to the diseased surface. (*Elém. de Pathologie Chir.* vol. v. p. 367, 368.)]

GLOSSOCATOCHUS (from *γλωσσα*, the tongue, and *κατέχω*, to depress). The ancient glossocatochus was a sort of forceps, one of the blades of which served to depress the tongue, while the other was applied under the chin.

[GLUCOHÆMIA or *Glycohæmia* (from *γλυκος* and *αἷμα*). *Saccharine blood* (Dr. H. Bennett, *Clin. Lec.* 1858). *Melitæmia* (Simon). *Glycosuria*. *Diabetes*. A disease in which the blood contains an excess of sugar, which percolates through the kidneys in solution with the urine. According to the recent researches of M. Claude Bernard, during health, a glucogenic substance analogous to hydrated starch is formed in the liver, and converted either by a ferment in the blood or by catalysis into grape sugar, to be decomposed in the pulmonary or systemic capillaries by the oxygen of the air; the transpositions being through dextrine to sugar, lactic acid, and finally to carbonic acid gas and water. A large quantity of organic matter is probably thus transposed very rapidly in the blood, the formation of the glucogenic substance being in some measure independent of the nature of the food. Glucogen is often derived, chiefly, if not altogether, from albuminous materials conveyed by the portal vein to the liver. In health, a few hours after meals a minute portion of sugar developed from this substance may sometimes be detected in the arterial or venous blood, but it does not occur in sufficient quantity to render the urine saccharine.

Although it has been shown experimentally that sugar in a dilute form introduced into the blood becomes decomposed and does not reappear in the urine, a temporary saccharine tendency of the blood, and a symptomatic diabetes, frequently occur. Neither the quantity nor the density of the urine in such cases is materially altered, but the morbid blood has the effect of an irritant, modifying the nutrition of parts, and producing scaly diseases of the skin, boils, carbuncles, or abscesses, which have sometimes been observed to precede or accompany confirmed diabetes. (*Prout*.) Or the sugar may be determined to other organs, as to the salivary glands, or the mucous membrane of the stomach or intestines. Sugar is also found in the urine of women during pregnancy, while nursing, and in childbed, having a direct association with the secretion of milk. (*Dr. H. Blot; Dublin Hospital Gaz. from Bullet. Gén. de Thérapeutique*.) It occurs also in various diseases of the brain and spinal cord, particularly such as are attended with convulsive movements; in dyspeptic and gouty individuals (*Prout*); in

diseases of the liver; and as an accessory symptom in other affections.

M. Bernard has shown, experimentally, that the formation of sugar in blood, as it is transmitted through the liver, is increased in animals by irritating the eighth pair of nerves at their origin in the fourth ventricle, or by piercing the upper part of the spinal canal; also that section of the eighth pair destroys this formation, but that it is restored and saccharine urine produced by artificially irritating the central cut extremities. He found also that whenever the respiratory function is violently stimulated sugar appears in the urine, and that the action of the Woorali poison, and the inhalation of ether and chloroform, occasion a temporary diabetes. Bernard explains the variations in the production of sugar by the liver, in these experiments, by variations in the abdominal circulation, produced by impressions made through the nervous system. Sugar is found in the urine also in marsh fevers, in greatest quantity at the commencement, and diminishing gradually towards the termination of the paroxysm. (*Burdell, L'Union Médicale*, No. 139, 1859.)

A doubt has been cast on the alleged sugar-forming function of the liver by Dr. F. W. Pavy (*Proceed. of the Royal Society*, vol. ix. p. 300), who regards the sugar found in the liver after death as a post-mortem formation. He states that blood drawn from the right ventricle during life contains scarcely an appreciable amount, although, when drawn from the same cavity after death, it contains a large proportion. This gentleman's experiments also tend to show that the sugar found in the hepatic system does not exist there during life; but he admits the formation by the liver of a substance which, in contact with complex nitrogenous materials, is convertible into sugar, designating this substance "hepatine." According to Dr. Pavy, with the destruction of life the transposition of hepatine into sugar takes place; and on sacrificing an animal by division of the lower part or crushing the centre of the medulla oblongata, and maintaining the circulation by artificial respiration, sugar can be made to appear in the urine. The conversion of hepatine into sugar during life, according to Dr. Pavy, is never a physiological, but always a pathological result.

In another series of experiments performed on dogs, Dr. Pavy found (*Guy's Hospital Reports*, vol. v. 1859, p. 204) that saccharine urine is produced, probably only temporarily, by the following lesions of the sympathetic system of nerves:—

Division of the lower part of the medulla oblongata, and artificial respiration;

Destruction of the medulla ob. through its centre, and artificial respiration;

Division of the ascending branches of the superior cervical ganglia on one or both sides;

Removal of one or both carotid ganglia;

Division of the thoracic sympathetic on one or both sides;

Decapitation and artificial respiration;

Deligation of the vertebrae and carotids, together with division of the contents of the vertebral canals on both sides;

Ligature of the carotids, and destruction of the parts in front and behind the transverse processes of the atlas in the vicinity of the foramen.

But that it is not produced by —

Separation of the brain from the med. oblong. at the crura cerebri;

Division of the spinal cord in the cervical region, and of both pneumogastrics;

Deligation of the carotids and vertebrae;

Division of the contents of the vertebral canals alone;

Division of the contents of the vertebral canals and of the structures around the carotids, leaving the arteries free.

Saccharine urine also occurred in poisoning with strychnine, with artificial respiration.

Mr. Harley subsequently performed a series of experiments which confirm Bernard's views (*On the Saccharine Function of the Liver, Proceed. of the Royal Soc.* vol. x. p. 289); and according to the doctrine at present prevailing, two products of cell-growth are simultaneously produced in the liver—sugar and bile: the sugar passes by diffusion into the blood by the hepatic veins, and the bile into the biliary ducts by filtration. Under certain pathological conditions, the sugar, from imperfect metamorphosis, in place of being consumed, is voided in the urine; just as the imperfect metamorphosis of the bile absorbed from the intestines is the result of certain pathological conditions of the liver or of the blood itself. (See art. PYÆMIA, TOXICOHÆMIA; also *Frerichs' Clinical Treatise on Diseases of the Liver*, New Syd. Soc. Ed. 1860.) But here this analogy ceases, inasmuch as the sugar is filtrated in solution by the kidneys as soon as formed; whereas the bile, at the stage of bile-pigment, accumulates in sufficient quantity in the blood to constitute jaundice.

Although glucohæmia belongs strictly to the domain of medicine, and for a full account we must refer to medical writers, it is sufficiently associated with injuries and surgical affections to demand the attention of the surgeon. Falls and injuries of the head, spine, hips, and loins, are often attended with saccharine urine. Since the promulgation of Bernard's views, tumors and concretions pressing on the par vagum have several times been found associated with diabetes. Suppurating skin diseases have been observed to dry up, and sores to heal rapidly, under the disease. Caries of the teeth is said to be common from the action of the saliva ferment in the grape sugar of the blood producing lactic acid. (*Falck, Edin. Monthly Journal*, Oct. 1854.) Diffuse cellular inflammation has been known to follow bleeding in diabetic patients (*Duncan*); and such subjects are especially liable to tuberculosis, and also to gangrene of the extreme parts of the body, several cases of spontaneous gangrene having been recorded.

The introduction of sugar of various kinds, including "diabetic" sugar, into the blood of animals has produced cataract (*Dr. Willshire, The Lancet*, Oct. 27, 1860), and glucohæmia is frequently the cause of cataract in the human subject. Mr. France cites twenty-one cases: he states, "The cataracts have in every example been symmetrically developed on both sides; the lenses have increased remarkably in their antero-posterior diameter, so as to encroach on the depth of the anterior chamber." "The colour and bulk of the cataracts have invariably indicated their soft consistence," and the affection has only arisen after considerable duration of the saccharine urine. Operations in the latter

stages of this disease have generally proved unsuccessful, and are of questionable propriety in any stage. (*On Diabetic Cataract*, by J. T. France, *Guy's Hospital Rep.* ser. iii. vol. vi.) A very remarkable case has been recorded in which cataracts alternated with this disease. (*Johnson's Med.-Chir. Rev.* Oct. 1827, p. 176.)

A saccharine state of the blood has been observed supervening jaundice, in which case the blood is cleared of the biliary pigment by the diuretic action of the sugar. In a case recorded by Frerichs the glucohæmia ceased entirely before the death of the patient, the kidneys were normal in their minute structure, but the pons Varolii and roof of the fourth ventricle were somewhat softened, and in their substance numerous little brown masses were found, the remains of capillary apoplexies. (Lib. cit. p. 149.)

The more prominent symptoms of diabetes mellitus are:—a dry, parched tongue, sometimes red and clean; heat, pain, and sense of sinking in the epigastrium; craving appetite; intense thirst; costiveness; for the most part a dry, rough skin, but sometimes profuse perspiration, the skin often exfoliating; the cuticle and sweat often of a sweet taste and odour; excessive secretion of urine with saccharine qualities; sugar sometimes found in almost all the fluids and tissues of the body; listlessness, aversion to exercise, depression of spirits, and general symptoms of debility; the temperature of the body lower than in health, with chilliness; hectic fever; and very marked atrophy.

The older authors describe diabetic blood as darker than natural, less coagulable, and its crisis or mixture accordingly loosened, and not separating into serum and clot, but too copiously dissolved and melted down (*Willis*), with an appearance of treacle. The results of modern analysis as to the proportions of the solid and fluid constituents vary greatly. It sometimes contains a greater and sometimes a smaller proportion of solids than in health, depending on its actual state when drawn from the vessels; influenced on the one hand by the discharge of a large quantity of fluid by the kidneys, and on the other by the quantity of fluid ingested to quench the thirst. The same circumstances must very materially influence the proportions, as determined on analysis, of the fibrin, albumen, and other substances. Upon the whole, these substances, and the solids generally, appear to be diminished. Rollo, Ambrosiani, Bouchardat, F. Simon, G. O. Rees, Müller, M'Gregor, and others, have shown, conclusively, that it contains sugar, which exists in it in very minute proportions at any one time, but is formed so rapidly and abundantly that the kidneys will sometimes separate, for long periods, upwards of a pound daily. It occurs in the larger quantity when blood has been drawn two or three hours after meals, and has been detected at that period, although, when drawn in the morning, no traces were visible. Glucogenic blood generally separates into a light-coloured, turbid serum, resembling whey, and a loose dark clot, or it may even be milky. Unaltered chyle has been found mixed with it, and almond-oil taken into the stomach has passed off by the kidneys without change. After death it is fluid, grumous, and black or chocolate-coloured, and Rollo and Babington (*Cyclop. Anatomy and Phys.* vol. i. p. 427) state that it possesses the peculiarity of resisting putrefaction longer than healthy blood.

The urine is sometimes enormous in quantity: as much as 13 or 14, 40, 52, and even 70 pints, or more, have been discharged in twenty-four hours. It frequently exceeds the total quantity of the solid and fluid ingesta. It is paler than usual; has sometimes a turbid, wheyish appearance with a greenish tint; an odour resembling that of new hay, or milk, or chloroform; and a specific gravity varying from 1025 to 1060. According to Schönbein there is no sugar in the earliest stages of the disease, but albumen. Albumen also appears sometimes to alternate with the sugar, and presents itself when the symptoms have been relieved by treatment. The quantity of sugar varies greatly; it may be from a few drachms to many ounces in twenty-four hours, sometimes appearing only during digestion, and it is not found in the kidney, but percolates through it in solution, a portion being always found in combination with chloride of sodium. It is occasionally insipid. The sugar gives the urine the power of deflecting the polarised ray to the right. The quantity of urea excreted appears to be variable: Kane found an excess; others have observed an apparent diminution. This variability is to be accounted for by the varying state of dilution of the blood and urine, although in the main a diminution might be expected from the atrophy of the tissues. Lithic acid crystals sometimes occur, but the proportion of lithic acid is subject to the same causes of variation. Sometimes, for a few days before dissolution, the excretion of sugar ceases.

Diabetes is more common in the male than in the female sex, and after than before puberty, although it sometimes occurs in children, and is frequently hereditary. The causes mentioned by writers are extremely numerous, but their *modus operandi* is not determined, and many of them are very doubtful. Probably the disease arises from causes of an opposite character. It is most frequent in cold, damp climates, and has been referred to suppressed action of the skin. By many it is considered as a disease of primary assimilation, produced, on the one hand, by long-continued excessive excitation of the digestive organs, as by the abuse of alcoholic fluids, and on the other by insufficient nutrition, living too exclusively on vegetable diet, and other depressing agencies. Others refer it almost exclusively to influences which depress the nervous energies. Prout and Bernard affirm that animals are not subject to the disease, which points to the influence of the mind. Either of these series of causes might produce a diseased state of the semilunar ganglion, or solar plexus, and of the organic nerves generally. A starch diet has been shown to produce diabetes in a few days. (*American Journal of the Medical Sc.* vol. xxxv. p. 469. *Hammond*). But that the starchy and saccharine principles of food are not the sole sources either of the sugar found in the liver physiologically, or that occurring in the urine, seems to be proved by these principles being converted in the liver into an emulsive mixture with fattening qualities, and also by the fact, that individuals deprived of all amylaceous diet, for long periods, have continued to excrete very large quantities of sugar. M. C. Bernard's opinion, that an excess of glucogen is formed in the liver, and that there is not a failure of oxygenation, since the effete nitrogenous elements of the blood become duly oxygenised, and urea occurs in urine containing a very large

quantity of sugar, has been extensively accepted. This is by no means inconsistent with the theory of the ganglionic system depressing or withdrawing its influence from the chylopoietic viscera, nor with the results of some of the recent experiments performed on that system of nerves. Diabetes frequently accompanies disease of the pancreas; out of nine cases Frerichs found atrophy, or fatty degeneration of this gland, in five. The arrest of chemical development of the glucogenic matter appears sometimes to take place at the formation of lactic acid as in saliva, or dextrine, constituting the disease called *diabetes insipidus*. Diabetes occurs frequently in the tuberculous habit, and many of its subjects die phthisical. The facts under the present head indicate some association between diabetes insipidus, albuminuria, diabetes mellitus, and tuberculosis.

The *treatment* of this disease, notwithstanding a better knowledge of its pathology, is still very unsatisfactory, and too frequently unsuccessful. Every effort has been made to obtain a favourable result by a modification of the diet. Macgregor, Rollo, and those who believed that the sugar is formed in the alimentary canal from vegetable substances, excluded all such substances, adopting a strictly animal diet. This treatment has often had a very decided effect in diminishing the quantity of urine and the amount of sugar; but experience has shown that it suspends these symptoms without curing the disease, and patients cannot endure it beyond a limited period. Even with such a diet the quantity of sugar will sometimes continue to increase, and all sudden changes of diet, even of an opposite kind, are attended with a temporary amelioration too frequently followed by a return of the symptoms in an aggravated degree. Complete deprivation of food causes the sugar to diminish or disappear, and in one case it disappeared for forty-eight hours after total abstinence, and did not reappear until three days after a gradual return to food. (*Andral*.) In addition to animal food, cruciferous and oleraceous vegetables, and gluten bread, have been recommended, but after a time patients tire of the last-mentioned substance. Dr. Camplin obtained a cure in his own person (*On Diabetes and its Successful Treatment*, second ed., 1860) by foregoing wine, bread, and everything saccharine or amylaceous, to the utmost possible extent, and adopting a *bran cake*, prepared in a particular way, by which the bran is reduced to a very fine powder, and is mixed with the smallest possible quantity of starch; using also fish, milk, fresh cruciferous vegetables, with abstinence from much liquid; tea in preference to coffee, toast-and-water, and, if any alcoholic fluid, claret, or pale French brandy. This diet, with warm clothing, sponging with tepid water, followed by friction, an occasional warm bath in winter, or sponging with cold salt and water in summer, change of air and occupations, and tonics, of which the effervescent citrate of ammonia and iron appeared to be the best, has been attended in his own and in other cases with the happiest results. Numerous cases, however, have resisted such a system of treatment. It has lately been shown that sugar itself, particularly substances consisting of glucose, as honey and fruits, may be administered to diabetics, to the extent of from five to eight ounces daily, not only without increasing, but with an abatement of the symptoms (*Dr. Budd, Med.*

Times and Gaz., May 22nd, 1858); and, according to Bernard's views, sugar may be employed on rational principles, inasmuch as it is converted in the liver into an emulsive substance, and by fattening serves to counteract the tendency to emaciation, the sugar of the disease being produced from albuminous substances. Caution is necessary, however, that sugar is not given in excess of the converting function of the liver.

Dr. Camplin's plan of treatment does not essentially differ from that which was resorted to previous to the recent doctrines as to the source of the sugar, and we find Bouchardat, Bernard himself, and Rayer, agreeing with Home, Rollo, and the most judicious of their predecessors, in proscribing amylaceous and saccharine aliments generally; not because they are the source of the sugar, but on account of their augmenting the activity of the liver and kidneys. Together with a system of diet, the advantage of attention to air and exercise cannot be overrated; hence the interior of hospitals, and the close dwellings and crowded streets of towns, are not favourable localities for the successful treatment of glucohæmia. The vapour-bath and hot baths, and especially the hot-air bath, or *sudatorium*, have been found highly beneficial. The too frequent failure of all modes of treatment has been referred to the influence of our cold and moist climate (*Ranking's Abst. of Med. Sc.* vol. i. p. 57); and those who believe the disease to be intimately associated with a state of suppressed perspiration place their reliance on diaphoretics. The skin becoming moist and soft is one of the earliest indications of amendment, the diminution of the saccharine excretion keeping pace with the improvement of the skin. Change to a warm climate has been especially recommended. Dr. Christie found the disease more manageable in Ceylon, and many cases recorded by Dr. Imray afford evidence of the beneficial influence of a tropical climate. (*Edin. Med. and Surg. Jour.*, Jan. 1845, p. 83.)

Dr. Gray, of Glasgow, adhering to the opinion that, in many cases at least, the sugar is produced in the stomach, recommends rennet in doses of a tablespoonful three, four, or six times a day, about half an hour after each meal, for the purpose of converting the sugar into lactic acid; administering alkalies at the same time to neutralise the acid. By the rennet the ultimate conversion of the sugar into carbonic acid and water is believed to be promoted, and several cases are given in confirmation of its efficacy.

Blood-letting, general and local, is advocated by Dr. Watts, of Glasgow, and others. When we consider that influences which augment the temperature and produce hyperæmia of the liver are followed by the production of glucohæmia, and also that, but for the excessive action of the kidneys, the blood-vessels would be loaded with imperfectly elaborated blood, the measure is feasible in the early stages of some cases; but it is not considered requisite or proper in old persons, in chronic cases, or where great debility has already supervened.

In the medicinal treatment there is no known specific. From the disease having its origin probably in various pathological conditions, each case requires to be studied *per se*. Opium, particularly in the form of Dover's powder, has been often found useful, and has sometimes been given with

advantage in very large doses. It quiets the nervous irritability, and diminishes the action of the kidneys, its influence in the latter respect being most conspicuous when it occasions profuse perspirations. It very probably also counteracts hyperæmia of the liver, its utility in this respect being explained by Bernard's experiments. Bitter tonics and alkalies are also often useful. The bicarbonates of soda and potassa have been found to diminish the quantity of sugar. The preparations of iron are often indicated, and the protoiodide and the *Tinct. Ferri Sesquichloridi* have proved particularly beneficial. Dr. Watson finds creosote useful; he considers that it checks the conversion of food into sugar. (*Lectures*, vol. ii. p. 611.)

GOITRE. See **THYROID GLAND.**

GONORRHŒA (from γονή, the semen, and ῥέω, to flow). Etymologically, an involuntary discharge of the semen; but always, according to modern surgery, a discharge of purulent infectious matter, from the urethra in the male, and from the vagina and surfaces of the labia, nymphæ, clitoris, urethra, and, as is alleged to have been made out by the late M. Cullerier, sometimes even from the lining of the uterus, in the female subject. (See *Dict. de Méd. et de Chir. Pratiques*, t. iv. p. 149.)

Dr. Swediaur, after censuring the etymological import, as conveying an erroneous idea, says, if a Greek name is to be retained, he would call it blennorrhagia, from βλέννα, mucus, and ῥέω, to flow. However, as most of the moderns consider the discharge as pus, not mucus, the etymological import of blennorrhœa is as objectionable as that of gonorrhœa. Mr. Howship has repeatedly examined the discharge with a microscope, but without perceiving any essential difference between such discharge and the pus effused from an ulcer. (*On Complaints affecting the Secretion and Excretion of the Urine*, p. 260.) In English, the disease is commonly called a *clap*, from an old French word *clapises*, which were public shops, kept and inhabited by single prostitutes, and generally confined to a particular quarter of the town, as is even now the case in several of the great towns in Italy. In German the disorder is named *ein tripper*, from dripping; and in French, *une chaudepisse*, from the heat and scalding in making water.

Mr. Wallace, of Dublin, objects to the terms gonorrhœa and blennorrhagia, and proposes to name the disease *catarrhal primary syphilis*. (*On Venereal Disease and its Varieties*, p. 233. London, 8vo. 1833.)

When an irritating matter of any kind is applied to a secreting surface, it increases that secretion, and changes it from its natural state to some other. In the present instance, it is changed from mucus to pus.

Till about the year 1753, it was generally supposed that the matter from the urethra, in cases of gonorrhœa, arose from ulcers in the passage; but about that time it was ascertained that pus might be secreted without a breach of substance. It was first accidentally proved by dissection, that pus might be formed in the sac of

the pleura, without ulceration: and Mr. Hunter afterwards examined the urethra of malefactors and others, who had been executed, or died, while known to be affected with gonorrhœa, and demonstrated that the canal may be entirely free from every appearance of ulcer.

The time when a gonorrhœa first appears, after infection, is extremely various. It generally comes on sooner than a chancre. Mr. Hunter had reason to believe that, in some instances, the disease began in a few hours; while, in others, six weeks previously elapsed; but he had known it begin at all the intermediate periods. However, it was his opinion that about six, eight, ten, or twelve days after infection, are the most common periods. In an immense majority of cases, MM. Ratier and Cullerier have found the period between the third and seventh day after coition as that in which a gonorrhœa most frequently commences. (See *Dict. de Méd. et de Chir. Pratiques*, art. **BLENNORRHAGIE**.)

The internal surface of the urethra is subject to inflammation and suppuration, from various other causes besides the venereal poison; and sometimes discharges happen spontaneously, when no immediate cause can be assigned. Such discharges may be called *simple* gonorrhœa, having nothing of a specific infection in them.

MM. Cullerier and Ratier assert that an intense gonorrhœa may occur from venereal excess, between two individuals whose genitals are perfectly sound, and that either one or both parties may experience the disorder. They declare that they have had many opportunities of verifying this fact. Amongst other patients, they visited one woman who apparently enjoyed perfect health, and yet communicated gonorrhœa to all who had connexion with her. They mention also a girl who gave a most severe clap to a young man, though she never had had any venereal complaint herself, and was found on examination to be quite free from disease. (See *Dict. de Méd. et de Chir. Pratiques*, art. **BLENNORRHAGIE**.) These statements agree with those made many years ago by several surgeons of the British army. (See **VENEREAL DISEASE**.) I may here observe, however, that the secretions from the pudenda may not be healthy, and yet no appearances of disease may admit of detection even by ocular examination of the parts.

Mr. Hunter knew of cases in which the urethra sympathised with the cutting of a tooth, and all the symptoms of a gonorrhœa were produced. This happened several times to the same patient. The urethra has been suspected to be sometimes the seat of gout; and Mr. Hunter was acquainted with instances of its being the seat of rheumatism. These occurrences MM. Cullerier and Ratier have never noticed, and when they do happen, are deemed by them to be merely accidental coincidences. (See *Dict. de Méd. et de Chir. Pratiques*, art. **BLENNORRHAGIE**.)

Mechanical and chemical irritations of the urethra, or of those surfaces of the female pudenda which are the seat of gonorrhœa, may excite a purulent discharge. Contusion and forcible distension of the female pudenda will bring it on. In cases of violation of female children, a discharge usually follows; and hence the person accused of the crime, is commonly alleged to have been guilty also of infecting the injured party. But it is of importance as a subject of medical jurisprudence

to be aware that the discharge frequently arises in the party violated from the causes above specified, without the prisoner having had any venereal complaint himself. Were this fact not remembered, a guilty person might be acquitted on the ground that he could not have infected the child, as it was ascertained that he had no disease about him.

Men who cohabit with leucorrhœal women, or at the period of the menses or lochia, often experience a discharge from the urethra, in consequence of such connexion. MM. Swediaur, Cullerier, and Ratier have all ascertained by experiments, that acute inflammation of the urethra, and a purulent discharge may be excited by injecting into the passage diluted liquid ammonia. (See *Dict. de Méd. et de Chir. Pratiques*, art. BLENNORRHAGIE.) What experienced surgeon is unaware of a discharge from the urethra being often excited by the mechanical irritation of bougies? These facts make it perfectly obvious, that a discharge from the urethra is not necessarily a venereal complaint, or in any way connected with a specific poison.

Although catarrhal syphilis (as Mr. Wallace terms gonorrhœa) occurs mostly on the mucous or muco-cutaneous surface of the genital organs, he remarks that it may take place on any surfaces of these descriptions to which the venereal poison has been applied, as those of the eye, rectum, &c. (See *Wallace on Ven. Dis.* p. 236.) This gentleman seems thus to advocate the identity of the poisons of syphilis, and one species of gonorrhœa; but he observes, that as "we are not at present acquainted with any symptoms upon which we can always rely with confidence to distinguish discharges produced by other causes of irritation, we must not think of attributing to this poison all, or even a majority of the discharges of this kind, which we meet with in practice." (*ib.*)

When a secreting surface has once received the inflammatory action, its secretions are increased and visibly altered. Also, when irritation has produced inflammation and an ulcer in the solid parts, a secretion of matter takes place, the intention of which, in both, seems to be to wash away the irritating matter. But, in inflammations arising from specific or morbid poisons, the irritation cannot be thus got rid of; for, although the first irritating matter be washed away, yet the new matter has the same quality as the original had; and, therefore, upon the same principle, it would produce a perpetual source of irritation, even if the gonorrhœal inflammation, like many other specific diseases, were not, what it really is, kept up by the specific quality of the inflammation itself. This inflammation seems, however, to be only capable of lasting a limited time, the symptoms peculiar to it vanishing of themselves, by the parts becoming less and less susceptible of irritation; and the subsequent matter can have no power of continuing the original irritation, for otherwise there would be no end to the disease. The time which the susceptibility of the irritation lasts must depend upon difference in the constitution, and not upon any difference in the poison itself.

Mr. Hunter believed that the venereal disease only ceased spontaneously when it attacked a secreting surface, and produced a mere secretion

of pus, without ulceration. Such were some of the sentiments of this great man, who was a firm believer in the identity of the poisons of syphilis and gonorrhœa; but this idea, and the hypothesis about the impossibility of any spontaneous cure of venereal sores, are now entirely relinquished.

Mr. Hunter also erroneously supposed that the poison of gonorrhœa and the venereal virus were the same. He thought he had seen all the symptoms of lues venerea originate from gonorrhœa only; he assures us that he had even produced venereal chancres by inoculating with the matter of gonorrhœa; and that he had repeated the experiment in a manner in which he could not be deceived. (p. 293, *et seq.*)

Mr. Hunter's experiments, however, have been repeated with a different result; but, as one of his advocates has remarked, can we wonder at this, when we consider from how many causes purulent discharges may arise, and how impossible it is to distinguish the venereal from any other? (*Obs. on Morbid Poisons*, by J. Adams, M.D. p. 91, ed. 2.)

In attempting to explain why a gonorrhœa, and a chancre do not equally produce lues venerea, and why the medicine which almost universally cures chancre, has less effect on gonorrhœa, one believer in Mr. Hunter's doctrine says that we must take into consideration that the seat of the two diseases is different; that the same cause may produce different effects upon different parts; that the same poison, when mixed with different fluids, may be more or less violent in its operation; and that there may be greater or less attraction of certain fluids to a part, according to its nature and composition. (*Inquiry into some Effects of the Venereal Poison*, by S. Sawrey, 1802, p. 4.) Mr. Sawrey truly remarks, p. 6, that if the gonorrhœal matter has clearly and decidedly produced chancre, or contaminated the system in any one instance, the question is determined. It could in no instance produce these effects unless it had the power of doing so. This writer brings forward some cases to prove that the poison of gonorrhœa may produce gonorrhœa or chancre: but the limits of this work only afford room to observe that these instances are by no means decisive of the point, because some objections may be urged against them, as, indeed, Mr. Sawrey himself allows.

Why does not gonorrhœa equally contaminate the system as chancre? In gonorrhœa, says Mr. Sawrey, the discharge is very plentiful; it is not, in general, attended with ulceration; the poison is much more diluted, and mixed with a mucous and puriform fluid. It is deposited in the urethra and its lacunæ, where little or no pressure is applied, and it finds easy egress out of the canal. In chancre there is breach of substance, the poison is not much diluted, &c.

Why does not chancre generally in the same person produce gonorrhœa, and gonorrhœa, chancre? Mr. Sawrey, in answer, expresses his belief, that these incidents are not very unfrequent. He says he has known persons having a chancre, which continued for months, become affected, after that time, with a clap, without any further exposure. His opinion is, that the matter of the chancre had insinuated itself into the urethra, and produced the disease; though he confesses, many

would explain the circumstance by supposing that the chancre and gonorrhœa were both communicated at the same time by two different poisons.

Mr. Hunter conceives that the presence of one disease renders the adjacent parts less susceptible of the influence of the other.

Another defender of this side of the question is Dr. Swediaur, who endeavours to prove the fallacy of the following positions:—1. *That the poison which produces the clap does never, like that of chancres, produce any venereal symptoms in the mass or lues itself.* 2. *That the poison of the clap never produces chancres, and that the poison of chancres never produces a clap.* 3. *That mercury never contributes to, nor accelerates, the cure of a clap; but that, on the contrary, every blennorrhagia may be certainly cured without mercury, and without any danger of leaving a lues behind.*

His arguments run thus:—the reason why claps do not, like chancres, constantly produce lues, is that most of them excite only a superficial inflammation in the membrane of the urethra, without any ulceration. Hence, absorption cannot easily take place, the poison being out of the course of the circulation. But he has seen claps with an ulcer in the urethra followed by the most unequivocal symptoms of lues itself. He mentions the urethra being defended with a large quantity of mucus, as the thing impeding the common formation of ulcers, which do occasionally occur when the mucus is not secreted as usual, or is washed away. He asserts that in many cases, where he had occasion to examine both parties, he was convinced that the chancres were communicated by a person affected with a simple gonorrhœa; and *vice versâ*, that a virulent clap had been the consequence of an infection from a person having merely chancres. He says that if a patient with a venereal running does not take care to keep the prepuce and glans perfectly clean, chancres will very often be produced. He owns that a great many claps are cured without mercury; yet, repeated experience has shown him a cure cannot always be thus accomplished. Mild cases, without ulcer or excoriation in the urethra, may certainly be radically cured without a grain of mercury; and though mercury should be given, it would not have the least effect; not because the disease does not proceed from the venereal poison, but because it is out of the course of the circulation. He contends that the topical use of mercury in injections acts usefully even in these cases. But, when a clap is joined with ulceration in the urethra, it is always cured more safely and expeditiously with mercury, and is frequently incurable without it. A lues also follows cases attended with ulcers in the urethra. He allows that all claps are not venereal. (See *Pract. Obs. on Venereal Complaints*, by J. Swediaur.)

The sentiments of Mr. B. Bell are quite at variance with those of Hunter, Sawrey, Swediaur, Adams, &c.; but, my limits will only allow me to enumerate a few of his leading arguments.

If the matter of gonorrhœa and that of chancre were of the same nature, we must admit that a person with a chancre only can communicate to another not only every symptom of pox, but of gonorrhœa; and that another with gonorrhœa only can give to all with whom he may have connexion chancres, with their various consequences. This ought indeed to be a very frequent

occurrence; whereas all allow that it is even in appearance very rare.

On the supposition of the matter of gonorrhœa and of chancre being the same, the latter ought to be a much more frequent occurrence than the former, from the greater ease with which the matter of infection must, in every instance, be applied to those parts on which it can produce chancres than that of the urethra, where, instead of chancre or ulceration, it almost always excites gonorrhœa. It is difficult to conceive how the matter by which the disease is communicated should find access to the urethra; while all the external parts of the penis, particularly the glans, must be easily and universally exposed to it; and yet gonorrhœa is a much more frequent disease than pox. Cases of gonorrhœa are in proportion to those of chancre, according to Mr. B. Bell's experience, as three to one. It is obvious that the very reverse should happen if the two diseases were produced by the same kind of matter.

The grand practical consideration, depending on the possibility of the venereal disease arising from gonorrhœa, is, whether mercurials should not be exhibited, in all cases, with the view of preventing such a consequence.

Waiving, on my own part, all attempts to decide the point, whether the matter of a chancre and that of one species of gonorrhœa, are of the same nature, I shall merely content myself with stating that, so far as my observation and inquiries extend, the majority of the best practitioners consider the exhibition of mercury unnecessary and consequently improper in gonorrhœa. This fact almost amounts to a proof that, if venereal symptoms do ever follow a clap, they are so rare, and I may add, always so imputable to other causes, that the employment of mercury, as a preventive, would, upon the whole, do more injury than benefit to mankind; and this, even admitting (what, in my mind, has never been unequivocally proved) that the matter of gonorrhœa is really capable, in a very few instances, of giving rise to the venereal disease. However, a few surgeons will not yet altogether renounce the employment of mercury in gonorrhœa. Thus, Mr. Wallace gives small doses of it with copaiba or cubebs, after the active inflammation has subsided. (See *Wallace on Ven. Dis.* p. 248.)

Mr. Carmichael, who is a believer in a plurality of venereal poisons, inculcates the doctrine that what he terms the *papular venereal disease*, or that which is characterised by a papular eruption, if the skin become affected, originates from a peculiar virus, which gives rise to gonorrhœa, and which is different from poisons supposed by him to excite other forms of the venereal disease. As, however, the simple primary ulcer, excoriation and gonorrhœa very frequently exist together, Mr. Carmichael suspects that they all arise from the same identical poison. (See *Essay on Ven. Dis.* p. 76, ed. 2. 8vo. Lond. 1825.) At the same time, this gentleman concurs in the common belief, that constitutional symptoms after a gonorrhœa are very rare. With regard to Mr. Carmichael's views, several facts present themselves. 1. The formation of excoriations and simple sores does not necessarily require the influence of any poison. 2. Sores, capable of imparting every form of constitutional syphilis, are now frequently believed by men of great experience, to present themselves in

the form of simple ulcers. 3. Numerous surgeons would ascribe the constitutional symptoms which, in a small proportion of cases, follow gonorrhœa, to the existence of venereal ulceration together with this disease, or at some period before or after it. 4. The facts that primary venereal sores of every description are capable of healing up spontaneously, and that some of them, being small and superficial, are therefore disregarded, and allowed thus to heal, are considerations which interfere considerably with some of Mr. Carmichael's ingenious conclusions. However, if it were proved that constitutional symptoms of a peculiar kind, like those specified by Mr. Carmichael, were limited to gonorrhœal cases, then there would be reason for suspecting that their nature must be determined by the influence of a poison not corresponding to that of other forms of the venereal disease.

[M. Ricord considers the poison of gonorrhœa distinct from that of syphilis, and will not admit that it is ever followed by secondary symptoms. Other French cotemporary surgeons of great experience, however, M. Vidal, M. Baumés, M. Réquin, maintain that gonorrhœa is occasionally succeeded by syphilitic infection of the constitution, and that one and the same poison is the cause of both chancre and gonorrhœa. I cannot agree with this latter opinion. I have frequently seen chancres resulting from accidental inoculation from a chancre, but have never seen a gonorrhœa so produced, even from a urethral chancre, nor have I ever observed a chancre to arise on the glans or prepuce from the matter of a gonorrhœa, with which these structures have been for weeks completely covered. On the other hand, the transference of secondary symptoms from one person to another, in which I thoroughly believe, added to the occasional occurrence of a concealed chancre, to my mind sufficiently accounts for the supposed cases of secondary syphilis as a sequela of gonorrhœa. (See SYPHILIS.)]

The first symptom of gonorrhœa is generally an itching at the orifice of the urethra, sometimes extending over the whole glans. A little fulness of the lips of the urethra, the effect of inflammation, is next observable, and soon afterwards a running appears. The itching changes into pain, more particularly at the time of voiding the urine. There is sometimes no pain till after the appearance of the discharge and other symptoms; and in many gonorrhœas, there is hardly any pain at all, even when the discharge is considerable. At other times, a great degree of soreness occurs long before any discharge appears. There is generally a particular fulness in the penis, and more especially in the glans. The glans has also a kind of transparency, especially near the beginning of the urethra, where the skin being distended, smooth, and red, resembles a ripe cherry. The mouth of the urethra is, in many instances, evidently excoriated. The surface of the glans itself is often in a half-excoriated state, consequently very tender; and it secretes a sort of discharge. The canal of the urethra becomes narrower, which is known by the stream of urine being smaller than common. This proceeds from the fulness of the penis in general, and either from the lining of the urethra being swollen, or in a spasmodic state. The fear of the patient, while voiding his urine, also disposes the urethra to contract; and the stream of urine is generally much

scattered and broken, as soon as it leaves the passage. There is frequently some degree of hæmorrhage from the urethra, perhaps from the distension of the vessels, more especially when there is a chordee, or a tendency to it. Small swellings often occur along the lower surface of the penis, in the course of the urethra. These Mr. Hunter suspected to be enlarged glands of the passage. They occasionally suppurate and burst outwardly, but now and then in the urethra itself. Mr. Hunter has also suspected such tumors to be ducts, or lacunæ of the glands of the urethra distended with mucus, in consequence of the mouth of the duct being closed, in a manner similar to what happens to the duct leading from the lachrymal sac to the nose, and so as to induce inflammation, suppuration, and ulceration. Hardness and swelling may also occur in the situation of Cowper's glands, and end in considerable abscesses in the perinæum. The latter tumors break either internally or externally, and sometimes in both ways, so as to produce fistulæ in perinæo.

A soreness is often felt all along the under side of the penis, frequently extending as far as the anus. The pain is particularly great in erections; but the case differs from chordee by the penis remaining straight. In most cases of gonorrhœa, erections are frequent, and even sometimes threaten to bring on mortification.

The natural slimy discharge from the glands of the urethra is first changed from a fine transparentropy secretion, to a watery whitish fluid; and the lubricating fluid, which the passage naturally exhales, becomes less transparent; both these secretions, becoming gradually thicker, assume more and more the qualities of common pus.

The matter of gonorrhœa often changes its colour and consistence, sometimes from a white to a yellow, and often when the inflammation is severe, to a greenish colour. When the inflammation is very high, shreds of lymph are sometimes discharged with the urine. (Wallace.)

These changes depend on the increase and decrease of the inflammation, and not on the poisonous quality of the matter itself; for an irritation of these parts, equal to that produced in a gonorrhœa, will produce the same appearances. Mr. Wallace finds that the less the inflammatory action, the less alkaline the discharge. (*On Venereal Diseases*, p. 244.)

The discharge is produced from the membrane of the urethra and from the lacunæ, but, in general, only for about two or three inches from the external orifice. Mr. Hunter says seldom further than an inch and a half, or two inches at most. This he terms the specific extent of the inflammation. Whenever he had an opportunity of examining a urethra affected with gonorrhœa, he always found the lacunæ loaded with matter, and more visible than in the natural state. Before the time of this celebrated man, it was commonly supposed that the discharge arose from the whole surface of the urethra, and even from Cowper's glands, the prostate, and vesiculæ seminales. But, if the matter were secreted from all these parts, the pus would collect in the bulb, as the semen does, and thence be emitted in jerks; for, nothing can be in the bulbous part of the urethra without stimulating it to action, especially when in a state of irritation and inflammation.

[Gonorrhœal inflammation may extend the whole length of the urethra, and even to the bladder itself. Sir A. Cooper describes the appearance of the urethra in a criminal executed while labouring under gonorrhœa, in the following terms : "For an inch and a half down, the urethra was exceedingly red, and there was some effusion of matter on the internal surface ; the urethra was red at the bulb, but not of so deep a colour. The inflammation, therefore, is not confined to an inch and a half down the urethra, but often extends over the bulb, and in this way produces strictures."]

When the inflammation is violent, some of the vessels of the urethra often burst, and a discharge of blood ensues. Sometimes such blood is only just enough to give the matter a tinge. In other instances erections cause an extravasation by stretching the part.

When the inflammation goes more deeply than the membranous lining, and affects the reticular, or spongy structure of the urethra, it produces in it an extravasation of coagulable lymph, the consequence of which is a chordee.

Mr. Hunter suspected that the disease is communicated or creeps along from the glans to the urethra, or, at least, from the lips of the urethra to its inner surface, as it is impossible that the infectious matter can, during coition, get as far as the disease extends. He mentions an instance in which a gentleman who had not cohabited with any woman for many weeks, to all appearance caught a gonorrhœa from a piece of plaster, which had adhered to his glans penis while he was at a privy abroad ; the infection is accounted for by supposing that some person with a clap had previously been to the place and had left behind some of the discharge, and that the above gentleman had allowed his penis to remain in contact with the matter till it had dried.

Many symptoms, depending on the sympathy of other parts with the urethra, sometimes accompany a gonorrhœa. An uneasiness, partaking of soreness and pain, and a kind of weariness, are felt about every part of the pelvis. The scrotum, testicles, perinæum, anus, and hips, become disagreeably sensible, and the testicles often require to be suspended. So irritable indeed are they in such cases, that the least accident, or even exercise, which would have no effect of this kind at any other time, will make them swell. The glands of the groin are often affected sympathetically, become swollen, and even occasionally suppurate, but not so generally as when they inflame from the absorption of chancreous matter. Mr. Hunter has seen the irritation of a gonorrhœa so extensive as to render the thighs, buttocks, and abdominal muscles painful. He knew one gentleman who never had a gonorrhœa without being immediately seized with universal rheumatic pains. Gonorrhœal rheumatism is now recognised as a frequent and severe complaint.

When the disorder, exclusive of the affections from sympathy, is not more violent than has been described, Mr. Hunter termed it a *common, or simple venereal gonorrhœa* ; but, if the patient is very susceptible of such irritation, or of any other mode of action which may accompany the venereal, then the symptoms are in proportion more violent. In such circumstances the irritation and inflammation sometimes exceed the specific

distance, and extend through the whole urethra. There is often a considerable degree of pain in the perinæum ; and a frequent, though not a constant, symptom, is a spasmodic contraction of the acceleratores urinæ and erectores muscles. In these cases, the inflammation is sometimes considerable, and goes deeply into the cellular tissue, but without producing any effect, except swelling. In other instances it goes on to suppuration, often becoming one of the causes of fistulæ in perinæo. Thus, Cowper's glands may suppurate, and the irritation often extends even to the bladder itself.

When the bladder is affected, it becomes more susceptible of every kind of irritation. It will not bear the usual distension, and therefore the patient cannot retain his water the ordinary time ; and the moment the desire of making water takes place he is obliged instantly to make it, with violent pain in the bladder, and still more in the glans penis, exactly similar to what happens in a fit of the stone. If the bladder be not allowed to discharge its contents immediately the pain becomes almost intolerable ; and even when the water is evacuated, there remains for some time a considerable pain both in the bladder and glans.

Sometimes, though rarely, when the bladder is much affected, the ureters, and even the kidneys sympathise ; and Mr. Hunter had reason to suspect that the irritation might be communicated to the peritoneum, by means of the vas deferens.

Mr. Hunter mentions a case in which, while the inflammatory symptoms of a gonorrhœa were abating, an incontinence of urine came on ; but, in time, spontaneously subsided.

A very common symptom attending a gonorrhœa is a swelling of the testicle. (See TESTICLE, DISEASES OF.)

Another occasional consequence is a sympathetic swelling of the inguinal glands. (See BUBO.)

A hard cord is sometimes observed leading from the prepuce along the back of the penis, and often directing its course to one of the groins, and affecting the glands. At the part of the prepuce where the chord takes its rise, there is most commonly a swelling. This sometimes happens when an excoriation and a discharge from the prepuce, or glans penis, exist.

Thus the symptoms of gonorrhœa in different cases seem to be subject to infinite variety. The discharge often appears without any pain ; and the coming on of the pain is not at any stated time after the appearance of the discharge. There is often no pain at all, although the discharge is in considerable quantity, and of a bad appearance. The pain often goes off, while the discharge continues, and will return again. In some cases, an itching is felt for a considerable time, which is sometimes succeeded by pain ; though, in many cases, it continues till the end of the disease. On the other hand, the pain is often troublesome, and considerable, even when there is little or no discharge. The neighbouring parts sympathise, as the glands of the groin, the testicle, the loins and pubes, the upper parts of the thighs, and the abdominal muscles. Sometimes the disease appears a few hours after the application of the poison ; sometimes not till six weeks have elapsed. Lastly, it is often impossible to determine whether

the case is a gonorrhœal discharge, or rather one produced by the application of infectious matter, or only an accidental discharge, arising from some unknown cause.

TREATMENT OF GONORRHOEA.

Mr. Hunter supposed that every form of the venereal disease arose from the same cause, and that, as we have a specific remedy for some forms, it might be conceived or expected this would be a certain cure for every one; and, therefore, that it must be no difficult task to cure the disease, when in the form of inflammation and suppuration in the urethra. But we have already explained that the poison of gonorrhœa is distinct from that of syphilis, and experience teaches us that gonorrhœa is most variable in its symptoms, while under treatment; and the most uncertain, with respect to its cure, many cases terminating in a week, while others continue for months under the same remedial means.

Whatever differences of opinion may be entertained respecting the cause of gonorrhœa, and particularly with regard to its being excited by the influence of a specific poison, its inflammatory nature cannot be overlooked; and it is this character of the disorder, which determines, in a great measure, the plan of treatment. The great indication, however, insisted upon by Mr. Hunter, was that of destroying the disposition and specific mode of action in the solids of the parts, and as they become changed, the poisonous quality of the matter produced will also be destroyed.

Gonorrhœa is incapable of being continued beyond a certain time in any constitution; and, when it is violent, or of long duration, it is owing to the part being very susceptible of such irritation, and readily retaining it. As no specific remedy for gonorrhœa is known, it is fortunate that time alone will effect a cure. Mr. Hunter was inclined to think medicine not of the least use, in nine cases out of ten. But even this would be of some consequence, if the cases, capable of being benefited, could be distinguished. Surgeons of the present day, however, have less despondency on this subject than the distinguished man whose opinion I have just now cited.

The means of cure, generally adopted, are of two kinds, internal remedies and local applications; but, whatever plan is pursued, Mr. Hunter inculcates the doctrine that we are always to attend more to the nature of the constitution, or to any accompanying disease in the parts themselves, or parts connected with them, than to the gonorrhœa itself.

When the symptoms are of the ordinary inflammatory kind, known by the extent of the inflammation not exceeding the specific distance, Mr. Hunter found stimulating applications less dangerous than when irritable inflammation is present: they seemed to him capable of altering the specific action; but, to produce this effect, their irritation must be greater than that of the original injury; and, as MM. Cullerier and Ratier observe, they must be tried at the very beginning of the case. The parts will afterwards recover of themselves, as from any other common inflammation.

Mr. Hunter believes, however, that in the beginning the soothing plan is generally the best. If the inflammation be great, and of the irritable kind, no violence is to be used, for it would only

increase the symptoms; and he states that nothing should be done that can tend to stop the discharge, as it would not put a stop to the inflammation.

But, if the disease has begun mildly, a stimulating injection may be used, in order quickly to get rid of the specific mode of action. This application will increase the symptoms for a time; but, when it is left off, they will often abate, or wholly disappear; and, after such abatement, mild astringents may be used, the discharge being the only thing to be removed.

When itching, pain, and other uncommon sensations are felt for some time before the discharge appears, Mr. Hunter diffidently expresses his inclination to recommend the soothing plan, instead of the irritating one, in order to bring on the discharge, which is a step towards the resolution of the irritation; and he adds that to use astringents would be bad practice, as by retarding the discharge they would only protract the cure. When there are stricture or swelled testicles, astringents should not be used; for, while there is a discharge, such complaints are relieved.

Mr. Hunter thus expresses himself in regard to the effect of mercury in gonorrhœa: "I doubt very much of mercury having any specific virtue in this disease, for I find that it is as soon cured without mercury as with it, &c. So little effect, indeed, has this medicine upon a gonorrhœa, that I have known a gonorrhœa to take place (while the patient was) under a course of mercury sufficient for the cure of a chancre. Men have also been known to contract a gonorrhœa when loaded with mercury for the cure of a lues venerea; the gonorrhœa, nevertheless, has been as difficult of cure as in ordinary cases."

Mr. Hunter does not say much in favour of evacuants, diuretics, and astringents, given internally. He allows, however, that remedies, which act specifically on the parts, as the balsams, conjoined with any other medicine, which may be thought right, may help to lessen the discharge, in proportion as the inflammation abates.

Local applications may be either internal to the urethra, external to the penis, or both. Those which are applied to the urethra seem to promise most efficacy, because they come into immediate contact with the diseased parts. They may be either in a solid or a fluid form. A fluid is only a very temporary application. The solid ones, or bougies, may remain a long while, but in general irritate immediately, from their solidity alone; and Mr. Hunter says the less bougies are used when the parts are in an inflamed state, the better. At present, bougies are rarely used in gonorrhœa, in consequence of their tendency to bring on a swelling of the testes.

The fluid applications, or injections, in use are innumerable, and gonorrhœa frequently gets well with many of various kinds. They often have an immediate effect on the symptoms, and hence must have power; though the injection which possesses the greatest power is unknown. As injections are only temporary applications, they must be used often, especially when found useful, and not of an irritating kind.

Mr. Hunter divides injections into four kinds, the *irritating*, *sedative*, *emollient*, and *astringent*. According to his doctrines, irritating injections of every kind, act in this disease upon the same

principle ; that is, by producing an irritation of another kind, which ought to be greater than the venereal ; by which means the venereal is destroyed and lost, and the disease cured, although the pain and discharge may still be kept up by the injection ; effects, however, which will soon go off, when the injection is laid aside. In this way bougies also perform a cure. Most of the irritating injections have an astringent effect.

Irritating or stimulating injections should never be used when there is considerable inflammation present ; especially in constitutions which are known to be incapable of bearing much irritation ; nor should they be used when the inflammation has spread beyond the specific distance ; nor when the testicles are tender ; nor when, upon the discharge ceasing quickly, these parts have become sore ; nor when the perinæum is very susceptible of inflammation, and especially if it formerly should have suppurated ; nor when there is a tendency in the bladder to irritation, known by the frequency of making water.

In mild cases, and in constitutions which are not irritable, such injections often succeed, and remove the disease almost immediately. The practice, however, ought to be attempted with caution, and not, perhaps, till milder methods have failed. Two grains of the bichloride of mercury, dissolved in eight ounces of distilled water, form a very good stimulating injection ; but an injection of only half this strength may be used when it is not intended to attempt a cure so quickly. If, however, the injection, even in that proportion, gives considerable pain in its application, or occasions a great increase of pain in making water, it should be further diluted.

Sedative injections will always be of service, when the inflammation is considerable, and they are very useful in relieving the pain. Perhaps the best sedative is opium, as well when given by the mouth, or anus, as when applied to the part affected, in the form of an injection. But even opium will not act as a sedative in all constitutions and parts ; but, on the contrary, often has opposite effects, producing great irritability. Lead may be reckoned a sedative, so far as it abates inflammation, while at the same time it acts as a gentle astringent. Fourteen grains of acetate of lead, in ℥viij. of distilled water, make a good sedative astringent injection.

Drinking freely of diluting liquors may have a sedative effect, as it in part removes some of the causes of irritation, by rendering the urine less stimulating to the bladder when the irritation is there, and to the urethra in its passage through it. The vegetable mucilages of certain seeds and plants, and the emollient gums are recommended. Mr. Hunter does not entertain much opinion of their efficacy, though some of his patients told him that they experienced less uneasiness in making water when their drink was impregnated with mucilaginous substances.

Emollient injections are the most proper, when the inflammation is very severe ; and they probably act by first simply washing away the matter, and then leaving a soft application to the part, so as to be singularly serviceable by lessening the irritating effects of the urine. Indeed, practice proves this ; for a solution of gum arabic, milk and water, or sweet oil, will often lessen the pain and other symptoms.

The irritation at the orifice of the urethra is frequently so great that the point of the syringe cannot be suffered to enter. In this case no injection should be used till the inflammation has abated ; but in the meanwhile fomentations may be employed.

Astringent injections act by lessening the discharge. They should only be used towards the latter end of the disease, and when it has become mild. But if the disease should begin mildly, they may be used at the very beginning ; for, by gradually lessening the discharge, without increasing the inflammation, we complete the cure, and prevent a continuance of the discharge called *gleet*.

The apprehension that injections give a tendency to inflamed testicle and stricture, has lessened very much the frequency of their use ; though it is to be suspected, with regard to strictures, that the long continuance of the discharge will be more likely than the injection to produce them. This opinion has been entertained by many good and experienced practitioners, and I observe that it is professed by Mr. Wallace. (*On Ven. Dis.* p. 251.) While much morbid sensibility exists, this gentleman prefers an injection, composed of 15 grs. of nitrate of silver to an ounce of water. When the sensibility has been lessened, he uses an injection of half a grain of bichloride of mercury to an ounce of water, or a grain and a half of the sulphate of copper ; or acetate of zinc.

On the principle of gonorrhœa being manifestly an inflammatory disorder, it is at first mostly treated at the present day by antiphlogistic means. In this country, however, we rarely take blood from the arm, unless the complications of the case require it, as may happen when the inflammation exceeds the specific distance, retention of urine comes on, or inflammation of the testicle occurs. In severe cases, leeches may be applied to the perinæum ; and the patient use the warm bath, hip bath, or bidet, under the influence of which he will be able to discharge his urine with comparatively little pain or difficulty. If there exists a state of active inflammation, Mr. Wallace applies leeches to the perinæum, or to the body of the penis, or to the internal surface of the prepuce, or to the glans in the neighbourhood of the frænum. "The leech-bites may be covered with a cataplasm, and allowed to bleed as long as convenient. When we wish to stop the bleeding, this may be done by touching the wounds made by the leeches with a pointed piece of nitrate of silver. Any ecchymosis produced in the penis or scrotum by the application of leeches quickly disappears." If the patient prefers it, Mr. Wallace sanctions puncturing one or more of the veins on the dorsum penis. (See *Wallace on Ven. Dis.* p. 247.) If any distress continue after the antiphlogistic treatment has been persisted in for a day or two, he observes that the greatest advantage will be derived from full doses of opium and henbane, combined with calomel. In the intervals between the periods of using the warm bath, the penis, scrotum, and perinæum, should be fomented with a decoction of poppy heads. The bowels are to be kept open ; a stimulating diet avoided ; and mucilaginous diluent beverages taken freely, with the view of rendering the secretion of the urine more abundant, and its quality less irritating to the urethra.

Many modern surgeons have relinquished the use of all injections in the treatment of gonorrhœa, and manage the disease on common antiphlogistic principles. Mr. Howship states that when injections are used, they are not unfrequently followed by a most distressing and permanent irritability of the bladder. (*On Complaints affecting the Secretion and Excretion of the Urine*, p. 268.) But the common objection to them is founded upon the suspicion that they increase the frequency of inflamed testicle and stricture.

Since Mr. Hunter's time many surgeons have been in the habit of keeping the penis, in the incipient inflammatory stage of gonorrhœa, covered with linen, continually wet with the liquor plumbi diacetatis dilutus; a practice which is certainly both rational and beneficial. Mr. Abernethy, in his *Lectures on Surgery*, speaks in favour of this method. And some surgeons have seen great relief derived from the use of a suspensor scroti, or double handkerchief, combined with rest and the elevation of the penis. A suspensory bandage is believed to lessen the chance of the testicles being attacked by inflammation.

For the relief of the ardor urinæ and irritable state of the bladder in gonorrhœa, opium, camphor, conium, and hyoscyamus, have been extensively employed. Sir Benjamin Brodie informs me that when the disease is attended with chordee, the vinum colchici frequently has beneficial effects. In consequence of this information, I have sometimes prescribed the vinum colchici, and found it useful in relieving the strangury, ardor urinæ, and irritable state of the bladder.

In the treatment of gonorrhœa, the liquor potassæ is a favourite internal medicine with many practitioners, who begin with prescribing it, and continue its use until the inflammatory stage has subsided. However, according to Mr. Howship, its effects are uncertain, and sometimes it excites uneasiness and irritation about the neck of the bladder, and difficulty of voiding the urine. Hence, whenever he directs this medicine, it is in combination with some aperient, so that it may not remain long in the bowels. (*On Complaints affecting the Secretion and Excretion of the Urine*, p. 269.)

When the glands of the urethra remain enlarged after all inflammation has subsided, mercurial ointment, or that of the iodide of potassium, may be rubbed on them.

In many strong plethoric constitutions, the symptoms are violent, and there is a great tendency to inflammatory fever. In such instances, opiate clysters, though at first productive of relief, sometimes increase the fever, and consequently aggravate all the symptoms. In those cases the balsam of copaiba also sometimes increases the inflammatory symptoms. In a constitution of this kind, the treatment consists chiefly in evacuations, the best of which are bleeding and gentle purging. The patient must live sparingly, and above all, use little exercise.

In a weak and irritable constitution the symptoms are frequently violent, the inflammation extending along the urethra, and even affecting the bladder. Here the indication is to strengthen; and according to Mr. Hunter, bark alone has been known to effect a cure. All evacuations are hurtful.

A fever has been known to stop the discharge,

relieve the pain in making water, and finally cure the disease. On other occasions, Mr. Hunter has seen all the symptoms of gonorrhœa cease on the accession of a fever, and return when the fever was subdued. In other examples, a gonorrhœa mild at first, has been rendered severe by the coming on of a fever, and upon its subsidence the gonorrhœa has ceased. Although a fever does not always cure a gonorrhœa, yet as it may do so, nothing should be done while it lasts. If the local complaint should continue after the fever is gone, it is to be treated according to symptoms.

A gonorrhœa may be considerably affected by the patient's manner of living, and by other diseases attacking the constitution. Most things which hurry or increase the circulation aggravate the symptoms; such as violent exercise, drinking strong liquors, eating high-seasoned, indigestible food, some kinds of which act specifically on the urethra, so as to increase the symptoms more than simply heating the body would do; such as pepper, spices in general, and spirits.

In cases which have begun mildly and in which the inflammation is only slight, or in others in which the violent symptoms have subsided, such medicines as have a tendency to lessen the discharge may be given, together with the local remedies before mentioned. Turpentine is the most efficacious, particularly the balsam of copaiba (See *Copaiba*) and cubebs. (See *Edin. Med. and Surgical Journ. for January, 1818, and for the same month, 1819; also, H. Jeffery's Pract. Obs. on Cubebs*, 8vo. Lond. 1821.) Of the latter medicine ʒij. may be given thrice in the twenty-four hours, or an equivalent dose in the form of capsules, essence, or watery extract may be preferred. But with respect to these and all other medicines, which act upon the disease through the medium of the urine, if they succeed at all, it is always within a week or ten days from the beginning of their use; and therefore if no amendment take place in this time, they should not be continued.

Bleeding from the Urethra is sometimes relieved by the balsam of copaiba. Mr. Hunter did not find astringent injections of use. Ice-cold water applied to the penis, scrotum, and perinæum, is one of the best expedients.

Painful Erections are greatly prevented by taking twenty drops of tinctura opii, or half a drachm of vinum colchici, at bedtime. Hemlock has also some power in this way; and many surgeons, among whom is Mr. Dunn, of Scarborough, have a favourable opinion of camphorated poultices, and of the internal exhibition of camphor.

Chordee.—When the inflammation is not confined merely to the surface of the urethra, but affects the corpus spongiosum, it produces in it an extravasation of coagulable lymph, as in the adhesive inflammation, which, uniting the cells together, destroys the power of distension of the corpus spongiosum urethræ, and makes it unequal in this respect to the corpora cavernosa penis, and therefore a curvature takes place at the time of an erection, which is called a *chordee*. The curvature is generally in the lower part of the penis. When the chordee is violent, the inner membrane of the urethra is so much upon the stretch, that it may be torn, and a profuse bleeding from the urethra excited, that often relieves the patient, and even sometimes proves a cure. This is the *inflamma-*

tory chordee; another kind has been named *spasmodic*.

In the beginning of the inflammatory chordee, bleeding from the arm is often of service; but it is more immediately useful to take blood from the part itself by leeches; for we often find that when a vessel gives way, and bleeds a good deal, the patient is greatly relieved. Exposing the penis to the steam of hot water frequently affords great relief. Poultices have also beneficial effects; and both fomentations and poultices will often do most good when they contain camphor. Opium, given internally, is of singular service; and if it be joined with camphor the effect will be still greater. Hyoscyamus will sometimes agree with the patient better than opium, or even than the acetate, or muriate of morphia; and frequently opium has the best effect, when administered in the form of an enema.

When the chordee continues after all inflammation has terminated, no evacuations are required; for the consequences of the inflammation will gradually cease on the absorption of the extravasated coagulable lymph. Mercurial ointment, rubbed on the part, will promote this event. When the common methods of cure are unavailing, hemlock is sometimes useful. Electricity is said to have been of service. A chordee is often longer in going off than any other consequence of a gonorrhœa, but, in the end, it disappears.

For bringing about the removal of the extravasated lymph, camphorated mercurial ointment is better than the simple unguentum hydrargyri. According to Mr. Hunter, *spasmodic chordee* is benefited by bark. (*On the Venereal Disease*, ed. 2.) The recent leaves of belladonna, powdered and made into an ointment with an equal weight of lard, and rubbed over the penis, are stated to hinder priapism, and relieve chordee, more effectually than any other application hitherto proposed. (*J. A. Paris, in Pharmacologia*, vol. ii. p. 110, ed. 5.)

Bladder affected.—Opiate clysters, the warm bath, and, if the patient is of full habit, bleeding, are proper. The excellent effects of the vinum colchici, as stated to me by Sir Benjamin Brodie, I have already noticed. Leeches may be applied to the perinæum. When this affection lasts a considerable time, and is not mitigated by common methods, Mr. Hunter advises trying an opiate plaster on the pubes or the loins, where the nerves of the bladder originate; or a small blister on the perinæum. A belladonna plaster would probably act more powerfully than one of opium. In another place, he mentions bark, hemlock, sea-air, and sea-bathing, among the proper means.

Swelled Testicle. See TESTICLE, DISEASES OF.

Retention of Urine. See URINE, RETENTION OF.

GONORRHŒA IN WOMEN.

Gonorrhœa in women is a much less painful complaint than in men, and less subject to complications, as bubo, retention of urine, &c. The complaint may not generally prevent the patient from following her usual occupations, and the menses are as little affected by it as it is by them.

The disease is not so easily ascertained in women as in men, because the former are subject to a disorder called *fluor albus*, or *leucorrhœa*, which resembles gonorrhœa. A mere discharge in wo-

men, is less a proof of the existence of a gonorrhœa than even a discharge without pain in men. The kind of matter does not enable us to distinguish a gonorrhœa from a *fluor albus*; for, in the latter affection, the discharge often puts on all the appearance of pus. Pain is not necessarily present, and therefore forms no line of distinction. The appearance of the parts often gives us but little information; "for," says Mr. Hunter, "I have frequently examined the parts of those who confessed all the symptoms, such as increase of discharge, pain in making water, soreness in walking, or when the parts were touched, yet I could see no difference between these and sound parts. I know of no other way of judging, in cases where there are no symptoms sensible to the person herself, or where the patient has a mind to deny any uncommon symptoms, but from the circumstances preceding the discharge; such as her having been connected with men supposed to be unsound, or her being able to give the disorder to others; which last circumstance, being derived from the testimony of another person, is not always to be trusted to, for obvious reasons." But, though there may sometimes be great difficulty in forming a judgment of some of these cases, the surgeon may frequently come to a right conclusion by recollecting, as Mr. Dunn has reminded me, that, besides the difference depending on the suddenly severe symptoms of gonorrhœa, *fluor albus* may be known by the great debility; the sinking of the stomach; the weariness of the limbs; the pain of the back, always increased by the erect posture; the severe headaches; the painful menstruation, together with the very gradual increase of the disease.

From the manner in which the disease is contracted, it must principally attack the vagina, a part not endowed with much sensibility. In many cases, however, it produces a considerable soreness on the inside of the labia, nymphæ, clitoris, carunculæ myrtiformes, and meatus urinarius. In certain cases, these parts are so sore that they will not bear to be touched; the person can hardly walk; the urine gives pain in its passage through the urethra, and when it comes into contact with the above-mentioned parts.

The bladder, and even the kidneys, occasionally sympathise. The mucous glands on the inside of the labia often swell, and sometimes suppurate, forming small abscesses, which open near the orifice of the vagina.

According to Mr. Hunter, the venereal matter from the vagina sometimes runs down the perinæum to the anus, and produces a purulent discharge, or even ulceration, in that situation. The disease in women may wear itself out, as in men; but it may exist in the vagina for years, if the testimony of patients can be relied on.

[*External or Vulvar Gonorrhœa*.—Gonorrhœa in the female may affect specially the external parts or surfaces, including all the structures exterior to the carunculæ myrtiformes, namely, the labia, the nymphæ, the clitoris, the preputium, the vestibulum, and the fossa navicularis. This form of the disease is usually termed vulvar gonorrhœa. It resembles in many respects what has been called external gonorrhœa in the male, affecting similar mucous surfaces of the glans penis and prepuce (*balano-posthitis*), and is equally amenable to treatment by simple local applications,

first of a soothing, and afterwards of an astringent character. In vulvar gonorrhœa the parts affected are red, more or less swollen and inflamed, their sensibility is much increased, and their surfaces often present excoriations, or even superficial ulcerations. Sometimes the labia, nymphæ, and preputium are considerably swollen and distorted by œdematous infiltration, and, in extreme cases, usually originating in neglect, the skin between the labia and thighs, as well as that of the inguinal regions, are excoriated, and exude a highly fetid purulent secretion. The attendant inflammation is not always confined to the mere surface, but occasionally invades the glandular structures of the vulva and the submucous cellular tissues, giving rise to phlegmonous and lacunar abscesses. The symptoms vary in degree according to the extent and severity of the attack. In simple cases they consist of itching, tenderness, scalding after micturition from the contact of urine, with, in some cases, uneasiness about the hips and perinæum; increased discharge, at first of mucus, afterwards of a muco-purulent, and lastly of a purulent secretion, accompany these symptoms. In the more severe cases the patient is unable to walk, from the excessive tenderness of the external parts, and it is with difficulty she can bear even the sitting position; the discharge is increased in quantity, becomes more acrid in quality, capable of excoriating the surfaces with which it comes in contact, and emits a peculiarly offensive odour. When lacunar or phlegmonous abscesses form, there are superadded to the above symptoms the localised throbbing pain, accompanied by pyrexia, which are usually associated with the formation of matter in the neighbourhood of the visceral outlets.

The treatment, where no abscess exists, consists in regulating and moderating the diet, in administering remedies to counteract inflammatory action. Saline aperients, with or without antimony, and sometimes anodyne medicines are all that is required. The abstraction of blood, by general bleeding, is seldom necessary, and the local application of leeches is inadmissible, both on account of the state of the parts and the fear of inoculation from the possible presence of an unobserved chancre, which might be concealed between or just within the carunculæ myrtiformes, and thus escape notice. The local treatment by soothing and mild astringent lotions will be found most efficient. Decoction of poppies, solutions of opium, or of preparations of morphia, will meet the former indication; the ordinary astringent metallic salts, such as the sulphate of zinc, the nitrate of silver, the acetate of lead, the sulphate of copper, of the strength of one or two grains to the ounce of water, or Goulard's lotion, of double strength, or a weak lotion of chlorinated lime or soda, will effectually meet the latter. Should abscesses form, emollient poultices may be applied; and when fluctuation becomes distinct, the abscesses should be freely opened, in order to prevent burrowing and the formation of fistulæ, which latter are otherwise apt to form, communicating either with the vagina or rectum, or with both. Should the mucous membrane be undermined by the abscess, portions of it may be advantageously removed. An abscess in the external labium should, as a general rule, be opened on its cutaneous surface.

Vaginal Gonorrhœa.—Gonorrhœal inflammation may extend from the vulva to the vagina;

but most frequently the disease commences in the vagina itself. The vaginitis resulting from gonorrhœal infection is not always to be detected by ocular inspection; but, in well-marked acute cases, by the aid of the speculum, increased vascularity will be observed, especially on the raised portions of the vaginal folds; occasionally ulcerated surfaces may be here and there seen; and when the disease has existed for some time, and has been severe, an appearance resembling the affection of the eyelids, termed granular lids, may, as a more rare occurrence, be noticed, indicating that the mucous follicles have become implicated. It is seldom that the submucous cellular tissue is invaded, but in exceptional cases phlegmonous abscess and even sloughing have supervened. The local symptoms are generally of a milder character where the vagina is the seat of the disease, than when the external parts are affected; and although the discharge is much more profuse in vaginitis, the patient's sufferings are infinitely less. However, in the onset of the attack, and in acute cases, the pains and uneasiness about the groins, hips, and pelvic region generally, are greatly complained of; but the excessive tenderness attendant on vulvitis is not experienced. In fact, in the majority of cases the inconvenience is so slight that the patient can hardly persuade herself that she is labouring under any more serious affection than leucorrhœa. Indeed, so much do the two affections resemble each other that it is often difficult even for the surgeon to diagnose correctly between them. The contagious nature of the discharge in all cases of gonorrhœa and its non-contagious character in most cases of leucorrhœa constitutes the principal difference; but this distinctive character is lost in severe cases of leucorrhœa, in which the discharge may from its acrid or irritating quality produce an inflammation and discharge in the male urethra resembling, in most of the accompanying symptoms, a severe gonorrhœa.

The treatment of gonorrhœal vaginitis should be general and local. The patient should avoid bodily exertion; her diet should consist of mild and for the most part farinaceous aliment; she should avoid all stimulants, and the only medicines usually required would be saline aperients, or other remedies directed against inflammatory action. The surgeon will depend more upon local treatment for the relief and cure of this affection. Amongst the local remedies, injections hold the first rank. While the inflammatory symptoms are present, these should be of an emollient and soothing character, or mildly astringent. The decoction of poppies, or weak opiate solutions, and the preparations of lead, form the best injections under these circumstances; the acetate of lead lotion, 1 gr. to the ounce, or the ordinary Goulard lotion, to which opiates may be added, answer exceedingly well. But when the inflammatory symptoms have subsided, and a profuse purulent discharge constitutes the prominent feature of the case, the more strongly astringent injections are to be preferred. The sulphate of alum; the nitrate of silver; the sulphate of zinc; the sulphate of copper, all form very efficient injections, beginning with the strength of 1 gr. to the ounce of water, gradually increased to 5 or 6 grs., as the disease becomes of older date, or when it assumes a chronic form. The vegetable astringents, such as the decoction of oak bark, of

elm bark; infusions of catechu or of kino, of hæmatoxylon, a solution of tannin from 1 to 2 drachms to a pint of water, or of a strong decoction of walnut leaves, answer exceedingly well, either alone or with the addition of some of the above-named metallic salts. The common injection for females at the Lock Hospital consists of oak bark, to which is added sulphate of zinc in the proportion of 6 grs. to the ounce. Should these injections fail to arrest the discharge, the direct application of the sulphate of copper or of the nitrate of silver to the surface of the vagina may be had recourse to. In applying these caustics, the speculum should be used, and the vaginal surface should be slightly cauterised from behind, forwards, as the speculum is being withdrawn. This should be done once every two or three days, and the application should be so made that the cauterised surfaces should alternate with the portions of the mucous membrane not receiving the caustic, so that, if possible, on removing the speculum no two cauterised surfaces should come in contact. Another efficacious plan of treatment, when the ordinary measures fail, is to secure the separation of the diseased surfaces of the vagina from each other; this is effected by plugging the vagina with lint or charpie after the passage has been well syringed with some of the above-named astringent injections, or after the caustic has been applied as above recommended. The plugging should be removed and replaced daily. To facilitate the removal of the plugs, some surgeons attach pieces of silk or twine to the dossils of lint or charpie previous to their being introduced; these are to be brought out at the vaginal orifice. I am myself satisfied with the use of long strips of lint, without threads attached, which are readily removed by the aid of the common dressing forceps. The bivalve speculum is the most convenient instrument to use for the purpose of introducing the strips of lint, or portions of charpie. In obstinate or chronic cases, the surgeon will often derive advantage from the internal administration of bark; of steel; the mineral acids, or of other tonic remedies combined with a more generous diet, and the moderate use of wine and other stimulants.

Uterine Gonorrhœa.—The inflammation attending a gonorrhœa will occasionally extend from the vagina and os uteri to the interior of the neck and body of the uterus; rendering the affection obstinate and tedious, resisting all the ordinary modes of treatment. This affection will be readily discovered by examination with the speculum. A peculiar glairy tenacious mucus will be seen, filling the cervix and os uteri, and depending from these into the vagina, and which is removed with difficulty on account of its extreme tenacity. Granular, or superficial ulceration of the os uteri is not an unfrequent accompaniment of this affection.

The treatment here required is to remove the tenacious mucus, so as to allow the injections or caustic to come into immediate contact with the diseased surface. This object is best effected by injecting from a large syringe, through the bivalve speculum, previously introduced, and by detaching the os uteri with dossils of lint, held by an appropriate forceps. When the mucus is completely removed, the nitrate of silver should be applied to the ulcerations on the os, if any exist, and should also be introduced into the cervix uteri. This treatment should be repeated every third or fourth day, but not during nor close upon a menstrual

period. On the intermediate days, common injections may be used by the patient herself, two or three times daily, in order to remove the vaginal discharge, which is certain to accompany the uterine affection. When, in spite of this treatment, the glairy discharge persists, the interior of the body of the uterus may be suspected as participating in the diseased action. Under these circumstances, the surface of the affected membrane must be reached. This must be done, however, with extreme caution. A narrow tube, fitting loosely in the neck of the uterus, may be introduced, and a small syringe, holding half an ounce only, should be attached to it. By an instrument of this kind a small quantity of an astringent lotion may be brought in contact with the mucous lining of the body of the uterus. The piston should be suddenly depressed, to allow the injection to pass out by jets, but of not more than a drachm at a time, and free egress should be allowed for the fluid by the side of the tube. Even with these precautions severe symptoms of abdominal pains, with chills and feverish symptoms, will occasionally follow injections into the uterine cavity. The great danger to be guarded against is the possibility of the injection entering into the Fallopian tubes, and from thence into the peritoneal cavity. Of the metallic salts, the sulphate of zinc, the sulphate of copper, or the nitrate of silver, of the strength of 1 gr. to the ounce, or a weak solution of a vegetable astringent, may be used for these intra-uterine injections.

Urethral Gonorrhœa.—The urethra may be affected by the disease in the female, but its occurrence is considered exceptional. The symptoms which accompany urethral inflammation resemble those in the male. Itching followed by pain in the urethra with scalding on micturition are experienced. The urethral orifice may be seen to be swollen and inflamed, and the whole course of the canal is felt to be thickened by digital examination. A purulent discharge will exude spontaneously, or may be made to appear by pressure exerted on the urethra from behind forwards. If the bladder become affected frequent desire to urinate is superadded to the other symptoms, but retention of urine is seldom present. A similar treatment to that adopted in the male subject may be had recourse to. The preparations of copaiba and cubebæ will be equally efficacious, and injections may be used, but they are generally dispensed with on account of the shortness of the canal and the close proximity of the bladder, which render it difficult to inject the one without the other. On this account some surgeons prefer cauterising the urethra with the nitrate of silver; this is, however, seldom necessary, the balsamic remedies acting with sufficient promptness and certainty. It should be borne in mind that urethral gonorrhœa is rarely found as an isolated complaint in the female; vulvitis or vaginitis will be usually found accompanying it, and they will of course require their appropriate treatments. The inguinal glands not unfrequently inflame and enlarge, but rarely suppurate in female urethritis.

Rectal and Anal Gonorrhœa.—From the position of the vulva and anus and the shortness of the intervening perinæum, the discharge escaping from the former must frequently come in contact with the latter, especially in the recumbent posture; notwithstanding this unfavourable proximity, it is

seldom that the anus or rectum becomes affected with gonorrhœal inflammation. Condylomata, accompanied by discharge, are not unfrequently observed in the neighbourhood of the anus both in male and female, but as a symptom of secondary syphilis and not of gonorrhœa. Inflammation and discharge arising from gonorrhœal infection in these parts only, must, I repeat, be considered of rare occurrence. When present and affecting the submucous tissue and skin at the verge of the anus, it resembles in appearance balanitis in the male or vulvitis in the female, being characterised by increased redness, and tumefaction of the parts affected, accompanied by excoriations and superficial ulcerations. When the external parts are alone implicated, local treatment by lead or other astringent lotions constantly applied, will speedily effect a cure. The disease, however, has been known to extend to the mucous lining of the rectum, giving rise to pain and a sensation of weight about the perinæum and anus, to tenesmus and painful defæcation, and a discharge of purulent matter from the rectum escaping by occasional jets rather than by a continual oozing. It must be borne in mind that both these affections occur as complications of and in association with gonorrhœa, occupying the more usual sites of the disease, the treatment of which must proceed simultaneously with that required for the rectum. The application of the nitrate of silver or of the sulphate of copper directly to the inflamed mucous surface of the rectum is the most efficacious plan of treatment after the inflammatory symptoms have been combated by the ordinary soothing and antiphlogistic remedies. Injections, if had recourse to, should be small in quantity, and the same as those recommended for vaginitis. Soothing injections of starch and opium will give relief in the first instance, while the inflammatory symptoms and those of excessive irritation exist. When these have subsided, those of an astringent character should be substituted.

The strength of the injections may be from one to two grains to the ounce of water of any of the metallic salts already mentioned, and as they should be retained, not more than two ounces in quantity should be used at a time, or some of the vegetable astringents may be preferred.]

GORGET. An instrument used in the operation of lithotomy, for the purpose of cutting the prostate gland and neck of the bladder, so as to enable the operator to introduce the forceps and extract the stone. It is, in fact, a sort of knife, at the end of which is a beak, that fits the groove of the staff, and admits of being pushed along it into the bladder. Besides cutting gorgets, constructed for the preceding design, there are also blunt ones, intended to be introduced into the wound, their concavity then serving as a guide for the forceps into the bladder.

GRANULATIONS. The little conical eminences which form on the surfaces of ulcers and suppurating wounds, and serve for filling up the cavities, and bringing nearer together and uniting the margins of ulcers and wounds, healing by what is termed the *second intention*. They receive their name from their granular appearance.

[Before the time of Hunter, the observation of surgeons led them to believe that unclosed wounds and ulcers were the seat of several successive processes, each capable of being hastened or improved by art:—these were digestion, cleansing, incarning, and cicatrising. Medicaments intended to promote the first process, usually of the turpentine sort, were called *digestives*, a name which survives to this day as an appellation for stimulating ointments. Digestion consists apparently in those processes which precede suppuration. Cleansing, or mundification, consists in the throwing off any films of imperfect fibrinous matter which may have adhered to the wound, and the remedies supposed to promote it, usually metallic solutions, as the oxymel æruginis, were called *detersives*. Incarning corresponds with granulating, and was wont to be promoted by *sarcotics*, of which myrrh, aloes, and sarcocolla were the most famous. Cicatrisation was promoted by *epulotics*. (*Turner's Art of Surgery*, vol. i. 1732.) Hunter, whose observations of matter of fact are above all praise, gives the following history of the origin and growth of granulations.] “I have often (says Mr. Hunter) been able to trace the growth and vascularity of this new substance. I have seen upon a sore a white substance exactly similar, in every visible respect, to coagulating lymph. I have not attempted to wipe it off, and the next day of dressing, I have found this very substance vascular; for, by wiping, or touching it with a probe, it has bled freely. I have observed the same appearance on the surface of a bone that has been laid bare. I once scraped off some of the external surface of a bone of the foot, to see if the surface would granulate. I remarked, the following day, that the surface of the bone was covered with a whitish substance, having a tinge of blue. When I passed my probe into it, I did not feel the bone bare, but only its resistance. I conceived this substance to be coagulable lymph, thrown out from inflammation, and that it would be forced off when suppu-

ration came on; but on the succeeding day, I found it vascular, and appearing like healthy granulations." [After Hunter's time, when surgeons began to occupy themselves with investigations of the minute processes of growth and disease, with very imperfect microscopes, there prevailed the idea, derived from Hunter's exaggerated solidism, that all organisation depended upon blood-vessels, and was effected by them; moreover, it was believed that pus globules were altered blood globules, and that the processes of inflammation and repair were to be explained in a mechanical kind of way.] Thus, Mr. J. W. Earle, in his inquiry into the nature of inflammation, gives the following explanation of the formation of granulations. "When the globules of the blood have been effused on the surface of a wound, it is clear that, after a time, their continued passage will have established an immense number of furrows, or canals, in that which was at first merely an amorphous layer or covering of fibrin, which canals must be the continuations of the genuine capillaries, and which, like them, must be wholly unprovided with distinct coats, like larger vessels. In proportion as these channels become established, the fibrinous layer is no longer in its original condition, but is pierced by innumerable perforations, which offer a readier egress to the serum and fibrin, as well as to the globules, so that at length nearly the whole of the discharge from the surface of a wound may find its way through them directly, instead of, as previously, by percolation. As the fresh fibrin exudes through the original layer by these channels, or perforations, it will coagulate around them in little heaps, whose central points must be the channels, or continuations of the genuine capillaries, through which it had exuded. As, on the one hand, the colouring matter of the globules was lost, in proportion to the difficulty with which they were forced by the pressure of the *vis a tergo*, through the parenchyma and fibrin, as yet imperforate, so, on the other hand, in proportion now as their passage is facilitated by the establishment of the above-mentioned canals, the globules will *advance further into the fibrin*, and approach nearer to the surface of the wound, *without being deprived of their colouring matter*. When this period has arrived, the fibrin, which was at first opaque, and of a dirty white colour, has assumed a jelly-like and more transparent appearance (in consequence of its combination with the serum, which is constantly passing through it), actually contains real blood, and has every character which pertains to granulations." (See *J. W. Earle, in Lond. Med. Gaz.* 1835, p. 219.) [But Sir E. Home, some years before, had pointed out the real process of exudation, and the formation of pus in it, in opposition to the theory which assumed that pus was but altered blood. He has the merit of showing the identity of pus and granulation, a notion ridiculed by Hunterians. (See *Phil. Trans.* part 1. 1829.)

From the time of Hunter to the modern microscopic era, the following were the doctrines usually taught respecting granulations.] The surfaces of granulations are very convex, the reverse of ulceration, and they present a great many small points, or eminences, so as to appear rough. The smaller such points are, the more healthy the granulations. The colour of healthy granulations is a deep florid red. When livid, they are unhealthy, and have

only a languid circulation. Healthy granulations, on an exposed or flat surface, rise nearly even with the surface of the surrounding skin, and often a little higher; but when they exceed this, and take on a growing disposition, they are unhealthy, become soft, spongy, and have no disposition to form skin. Healthy granulations are always prone to unite to each other, so as to be the means of uniting parts.

They are not endowed with the same powers as originally formed parts. Hence they more readily ulcerate, and mortify. The curious mode in which granulations contract, when sores are healing, and even for some time after they are healed, has been explained in the article *CICATRISATION*. (See *Hunter on the Blood, Inflammation, &c.* p. 473, *et seq.* 1794.)

It was a question whether granulations can ever be formed without suppuration. Mr. Hunter seemed inclined to think that they may occasionally be produced without it, and he supported his opinion by the relation of the dissection of a limb which had suffered a compound fracture, and in which he observed a substance resembling granulations. Dr. John Thompson, on the other hand, declares that he has never seen any granulation, and still less a granulating surface, where pus was not formed. (See *Lectures on Inflammation*, p. 408.)

The exact process by which the blood-vessels, nerves, and absorbents of granulations are formed, is still amongst the secrets of nature. The observations of Mr. Hunter on the subject amount only to conjecture. "The growth of nerves, and their development in granulations (says Dr. J. Thompson), is a subject of equal curiosity with the growth of blood-vessels in the same structure. Their existence in granulations is proved by the pain which is felt on our pinching, rubbing, or wiping the surface of a sore. Even the granulations which arise from the surface of bone are sensible; and the same granulations are in the course of a few hours provided not only with blood-vessels and nerves, but also with a system of absorbents. The existence of absorbents in granulations is proved, not only by the changes of bulk which we see them daily undergo, becoming gradually, in the healthy state, smaller, firmer, and more compact, but also by the frequent disappearance, in whole or in part, of a granulating surface, by the process of ulcerative absorption." (See *Thompson's Lectures on Inflammation*, p. 419.) According to Sir Astley Cooper, granulations which spring from parts endued with great sensibility, like muscles, are extremely sensitive; but granulations which arise from bones, he says, have no sensibility whatever. These observations are qualified with the condition, that the bone be uninflamed, and it is acknowledged that granulations, arising from the cancellated structure of bones, are sometimes extremely sensitive. He describes granulations from tendons as quite insensible, and those from aponeuroses and fasciæ as possessing very little sensibility. Every young dresser of sores at an hospital, who has been too lavish of the red precipitate ointment, must have learned from experience that granulations are furnished with absorbent vessels, and that mercury may be absorbed from the surface of ulcers, and bring on an unwished-for salivation of the patient. Indeed, the absorbent power of granulations is frequently the means of producing baneful

effects upon the constitution, by the introduction of deleterious substances into the circulation. Thus, arsenic, applied to sores, is often conveyed into the system, and, on this account, is to be regarded as a dangerous external remedy. Sir Astley Cooper quotes one instance, in which the patient seems to have been poisoned by the indiscriminate application of arsenic to a fungus of the eye. Opium also, when applied to the surfaces of sores, is very readily absorbed, producing similar effects to those which arise from its introduction into the stomach. Thus, when the quantity absorbed is too great, excessive costiveness, extreme pain in the head, and torpor of the system, are the consequences, which require the frequent administration of active purgatives for their removal. A temporary amaurosis has been known to be produced by the absorption of the extract of belladonna from the surface of irritable malignant ulcers. (*F. Tyrrell; A. Cooper's Lectures*, vol. i. p. 169.)

[The reader will notice the unfounded assumption of the development of nerves in granulations because they are sensitive, and the still more extraordinary assumption of the existence of lymphatic vessels, on the ground that granulations are capable of altering in volume, of perishing by disintegration, and of imbibing liquid medicines applied to their surface. (See ABSORPTION.)

If we may give, as shortly as possible, a *résumé* of the more modern observations on this matter, we may say that granulations appear to consist of a portion of the plastic matter of the blood employed for the reparation of such wounds as do not heal by the first intention. Their common situation is in suppurating wounds or healing ulcers of the skin, and they are commonly found in diseased joints; but Mr. Paget confirms Hunter's observation, that they may exist without suppuration. "In subcutaneous injuries or diseases (he says), granulations sometimes form, which develop themselves into cellular tissue through nucleated blastema. So I found in a case of simple fracture, in which the ends of the bones remained long disunited; they were enclosed in a cavity formed by condensation of surrounding tissues, but containing no pus, and were covered with a distinct layer of florid granulations." (*Lectures on Surgical Pathology*, vol. i. p. 208, Lond. 1853.)

Supposing an injury which leaves various cut surfaces exposed. First there ensues a period of repose, during which the wound is covered with a whitish glaze, and a serous oozing (or *quitture*, as our fathers called it) takes place. Then, in three, four, or more days, a translucent whitish substance, not a mere film or glaze, but a something succulent, covers the wound, and within twenty-four hours assumes a rosy, and then a decidedly red tint. During the period of repose, it is supposed by Mr. Paget that the blood-vessels are enlarging, and preparing to pour out the exudation.

The exudation develops itself into nucleated cells, now well known as *plastic* or *fibro-plastic*, or granulation cells. They have strong resemblances to the white corpuscles of the blood, and to pus cells. They are described by Mr. Paget as at first "spherical, palely or darkly nebulous, from about $\frac{1}{1800}$ to $\frac{1}{2500}$ of an inch in diameter. They contain a few shining, dark-bordered granules, and lie imbedded in a variable quantity of clear pellucid substance by which

they are held together." These cells develop themselves into filamentous tissue, by the processes of elongation and splitting. "Singly (says Mr. Paget) they are colourless; but in clusters they are ruddy, even independent of the blood-vessels. In granulations that are making healthy progress,—in such as, after three or four days' growth, are fluid, moist, level, scarcely raised above the surrounding tissues, uniformly granular, or like a surface of minute papillæ,—one can conveniently trace the cells in various stages, according to the position they occupy. The deeper seated ones are always most advanced, and often much elongated or nearly filamentous; while the superficial ones are still in a rudimental state, or near the edges of the granulating surface are acquiring the character of epithelial cells."

The surface of granulations is usually bathed in pus. This liquid appears to consist of the same exudation as forms granulations, with the cells misdeveloped into pus cells, and the intercellular substance melted down into the *liquor puris*. A profuse suppuration, and consequent waste of material, is usually a sign that the healing process is prevented by some constitutional or local irritation.

As we have already narrated, Mr. Paget believes that some *subcutaneous* injuries are repaired by a material which sets at once into a fibrillary state (*nucleated blastema*) without going through the process of cell development. (See REPAIR, WOUNDS.)

The formation of new vessels in granulations has always excited the admiration of the pathologist. The process has been accounted for in one of two ways. It has been supposed, for example, that in the new *blastema* or reparative material effused, blood and blood-vessels are formed, as they are in the embryo, and that the new blood-vessels so formed join themselves to those of the parent body. (See *Wedl; Pathological Histology*, Sydenham Society, p. 81; *Schwann and Schleiden*, *ib.*)

The other view, which is adopted by Mr. Paget, is, that the capillary vessels of granulations are outgrowths of the vessels of the part on which the granulations are situated, and from which they were exuded. Little vessels shoot out into the new layer of granulations, and inosculate in every direction, forming arches, from whose convexity again fresh shoots are given off. Mr. Paget believes likewise that petty streams of blood may exude into the granulation material, and that vessel walls may be formed around these.

However formed, the vessels should be numerous enough in healthy granulations, to give a florid surface, covered with a succulent layer, which the eye soon learns to recognise as healthy. Sometimes the granulations seem very small and irritable, and the vessels too numerous; more often, on the contrary, they are too large, pale, puffy, and exuberant, and defective in vascular supply. Or they may be exuberant and vascular likewise, secreting pus profusely, as happens sometimes when patients with ulcerated surfaces consume too much meat and beer.

Neither nerves nor lymphatics have been found in granulations. The assumption of their existence by the surgeons of the foregoing generation was an effect of the want of a proper system of philosophising in medicine, and of imperfect observation, which did not include general and comparative physiology.

The chemical composition of granulations is said to be albuminous, like that of lymph and pus, passing into the gelatinous as it becomes more fully developed into skin and areolar tissue. They constitute, as it were, a transition stage; and when their surface is converted into epithelium, their function is discharged, their vessels shrink, and they lose their identity in the scar or cicatrix which succeeds.

The surface of granulations, and the exudation which they yield, instead of *healing* or becoming developed into cuticle, sometimes remains in a permanent state, constituting the condition known as *indolent ulcer*, lining membrane of *sinus*, &c. During any period of weakness, and especially at the approach of death, they are apt to break up into a sanious liquid, or, in the old phraseology, to *ulcerate afresh*.

Granulating surfaces readily cohere together; thus the opposite portions of a wound which have not united by the first intention, and which are covered with healthy granulations, will often unite by organic union, when these granulating surfaces are applied one to the other and so kept. This is called healing by the second intention, or by the inosculation of granulations.] *R. Drutt.*

GUNSHOT WOUNDS AND INJURIES receive their name from the manner in which they are produced, being generally caused by hard, obtuse, metallic bodies, projected from cannons, muskets, or other species of firearm. With such injuries, it is also usual to comprehend a variety of dreadful accidents arising from the explosion of shells, or the violence with which pieces of stones from ramparts, or splinters of wood on board ship, are driven about. Gunshot wounds are the most considerable of the contused kind; and what is to be said of them will apply, more or less, to all contused wounds, according to the degree of contusion. The effects of a gunshot wound differ so materially in different men, and the appearances are so various, according to the nature of the part wounded, and the greater or lesser force with which it has been struck, that no invariable train of symptoms can be laid down as its *necessary* concomitants. If a musket or pistol-ball has struck a fleshy part, without injuring any material blood-vessel, we see a hole about the size of, or smaller than, the bullet itself, with a more or less discoloured lip, forced inwards; and, if it has passed through the parts, we find an everted, less livid, more ragged, and larger orifice at the point of its exit. The hæmorrhage is in this case very slight, and the pain may be inconsiderable, insomuch that, in many instances, the wounded man is not aware of his having received any injury.

[It is not, however, always practically an easy matter to distinguish the wound of entrance from that made by the escape of the ball, by the character of the edges alone. The margins of the wound at the point of entrance are not in every, nor even in the majority of the cases inverted, nor are those of the point of exit of the bullet always everted. If the speed of the ball has been swift, especially if it be a conical one, and no bone has been struck so as to impede the velocity of the missile, then there is but little characteristic difference either in the size or appearance of the two wounds. The margins of the escape wound are sometimes undermined when produced by a bullet having little original velocity, or from having

had its velocity diminished by contact with, or transmission through, bone; this is due to the natural resistance or toughness of the skin, yielding or being lifted up by the ball before it is actually torn, and it is this peculiar elasticity and toughness of the integument which causes these projectiles to be often arrested in their flight when nearly spent; so that it is a very common occurrence to have to cut down upon and extract balls, lying immediately beneath the skin, on the side of the limb opposite or nearly opposite to the point of entrance.]

If the ball has torn a large vessel, or nerve, the hæmorrhage will generally be profuse, or the pain of the wound severe, and the power of the part lost. Some men will have a limb carried off, or shattered to pieces by a cannon-ball, without exhibiting the slightest symptoms of mental or corporeal agitation; nay, even without being conscious of the occurrence: and when they are, they will coolly argue on the probable result of the injury; while a deadly paleness, instant vomiting, profuse perspiration, and universal tremor, will seize another on the receipt of a slight flesh wound. This tremor, which has been so much talked of, and which to an inexperienced eye is really terrifying, is soon relieved by a mouthful of wine or spirits, or by an opiate; but, above all, by the tenderness and sympathising manner of the surgeon, and his assurance of the patient's safety." (See *Hennen's Principles of Mil. Surgery*, p. 33, edit. 3.)

On the other hand it is correctly noticed by Mr. Guthrie, that the continuance of the constitutional alarm, or shock, ought to excite great suspicion of serious injury; and when wounds have been received in such situations, or bear such appearances, as render it doubtful whether any parts of vital importance have been injured, or not, the manner in which the constitutional perturbation lasts may be assumed as evidence of the fact, when other symptoms more indicative of the injury are wanting; and, under all such circumstances, a very cautious prognosis should be delivered. (*Commentaries of Surgery*, p. 3, ed. 6.)

Respecting the general tendency of gunshot wounds not to bleed copiously, unless large vessels be injured, it is a fact which necessarily depends upon the degree of contusion usually attending these injuries. But it is also true, as the preceding author has stated, that, although some gunshot wounds bleed but little at first, there is in the greater number of cases more or less of blood; and in wounds of vascular parts, like the face and neck, the quantity lost is often considerable, though the main arterial branches may not be injured. (*Op. cit.* p. 1, ed. 6.)

In gunshot wounds another circumstance is observed, which is often remarked in other cases, viz., when a large artery is partially divided, the bleeding is more profuse and dangerous than when the vessel is completely severed, and the hæmorrhage, if not repressed by a tourniquet or other means, will often continue until the patient dies. Thus Mr. Guthrie speaks of three cases, in which life was lost from wounds of the femoral, brachial, and carotid arteries, no effectual means of stopping the hæmorrhage having been adopted. In 1830, a young man, at the attack on the Hôtel de Ville, in Paris, received a ball in the upper and inner part of the right thigh, and the femoral artery was wounded; he was conveyed to the Hôtel-Dieu, but lost so much blood in the streets that, when he

reached the hospital, he was in a dying state. (*Dupuytren, Clin. Chir. t. ii. p. 464.*)

[Cannon-balls, and even bullets, sometimes produce severe internal lesions without occasioning a breach of continuity in the integument. These injuries before the time of Ambrose Paré (who was the first to explain correctly the manner of their production) were termed wind contusions. The muscles, bones, or solid viscera may be bruised, broken, or crushed by these missiles, or hollow viscera may be ruptured without leaving any appearance of injury on the surface of the skin, sometimes not even discoloration.]

Such cases were for a long while imputed to the violent motion supposed to be communicated to the air by the ball itself. It was imagined that this elastic fluid, being rapidly displaced by the shock of the projectile, was capable of making such pressure on surrounding bodies as to destroy their texture.

[Some experiments have been recently made by M. Pelikan to determine the influence which a cannon-ball produces on the surrounding atmosphere in its rapid flight through it. He had a machine constructed for measuring the force exerted by the wind of balls passing at various distances. At three inches from it, the passing ball produced not the slightest effect; after repeated experiments the results attained were constantly the same. His conclusions are: 1. That a projectile passing very close to any object exercises only an insignificant influence upon it. 2. That which is called the wind of a ball, even with a full charge of powder, has so trifling a force, as to be incapable of determining any lesion, even with pieces of large calibre.]

The mischief, formerly imputed to the air, is occasioned by the ball itself. Its producing a violent contusion, without tearing the skin and entering the limb, is to be ascribed to the oblique direction in which it strikes the part, or, in other instances, to the feebleness with which the ball strikes the surface of the body, in consequence of its having lost the greater part of its momentum, and acting principally by its weight, being, in short, what is called a spent ball. Daily observation evinces that balls which strike a surface obliquely, do not penetrate, but are reflected, though they may be impelled with the greatest force, and the body struck may be as soft and yielding as water. This alteration in the course of the ball, not only happens on the surface of the human body, but also in the substance of a limb which it has entered. Thus a bone, a tendon, &c. may change the direction of a ball which touches them at all obliquely. Hence, the track of a gunshot wound is not always straight, and balls sometimes run under the integuments nearly all round the body or limb.

A ball, when it strikes a part of the body, may cause several kinds of injury. 1. It may only occasion a contusion without penetrating the part, on account of its being too much spent, or of the oblique way in which it strikes the surface. 2. It may enter and lodge in the substance of a part; in which case the wound has only one aperture. 3. It may pierce through and through; and then there are two openings, one at the entrance, the other at the exit of the ball. At the entrance there is commonly more contusion and ecchymosis than at the exit of the ball. The former opening is generally narrower; the latter wider and more irregular,

especially when the ball has been flattened by its having struck a bone. The aperture made by the ball in the clothes is always much narrower than that occasioned in the corresponding integuments. 4. A cannon-ball, or large fragment of shell, may tear off a whole limb.

As is observed by a most eminent practitioner, the effects of gunshot wounds depend very much upon the manner in which the gun has been loaded, and the distance at which it has been discharged. If a fowling-piece is merely loaded with powder, without any wad, and fired off very near the person who receives injury, the integuments are violently contused. But, if the same charge be rammed down, the effects will differ according to the degree of resistance and the distance of the wounded party. The following case occurred in the practice of Dupuytren. Two persons quarrelled; and one of them discharged a fowling-piece, loaded only with powder, at the abdomen of his adversary, who instantly fell dead. The mouth of the gun had been not more than a foot or two from him. Dupuytren, having been juridically required to ascertain the cause of death, found the clothes torn, a hole in the parietes of the abdomen more than an inch in diameter, the intestine wounded, and the wad in the middle of the abdomen. Parties attempting suicide sometimes, in their confusion, forget to put the ball into the pistol. The explosion occasions a violent distension of the parietes of the mouth; and though the vertebral column is not injured, the soft palate is lacerated, and sometimes the lower jaw fractured. (*Dupuytren, in Clin. Chir. t. ii. p. 419.*)

The many accidents which occur in the shooting season, should lead every surgeon to remember that small shot acts in two ways: it either strikes in a mass, "*il fait balle*," as the French term it, which depends upon the goodness of the fowling-piece and its nearness to the wounded person, or else it is scattered, and each shot hits separately. In the first case its effects are generally more formidable than those of a single bullet. (See *Dupuytren, ib.*) I lately visited, with Mr. Broxholm of Sunbury, a young man who, in taking a fowling-piece out of a cart, received its contents at the inner and upper part of the arm, the mouth of the gun being at the moment close to the limb. The shots in a mass passed obliquely through it, on the outer side of the humerus, occasioning an opening at their entrance not more than an inch and a half in diameter, but one at their exit much larger, and of an irregular triangular shape. This case was not followed by any very severe consequences; a circumstance to be ascribed partly to the patient's good constitution, and partly to the fortunate circumstances of the bone, as well as other important parts having escaped injury, and no foreign body having lodged in the part. The wound was, however, attended with more laceration than one caused by a single bullet would have been.

Angular, uneven bodies, such as pieces of iron, hammered leaden bullets, cut lead, fragments of shells, &c., produce far more dangerous wounds than round smooth balls. Several persons were wounded at Paris, in the late disturbances, by irregular pieces of balls, which had been broken by striking first against iron bars. (*Clin. Chir. t. ii. p. 429.*)

In sieges, many severe injuries are produced by fragments of stones and brickwork being driven

about with immense violence, on being struck by cannon-balls. Even the ground itself is frequently scattered with such force as to cause injuries of a serious nature. Several examples of such occurrences are noticed by M. Larrey, jun. (See *Hist. Chir. du Siège de la Citadelle d'Anvers*, p. 42, &c.) Irregular angular bodies keep up inflammation until they are discharged in the course of the suppuration, or they are extracted. But the textures sometimes become habituated to the presence of a ball, which is regular and smooth, and not of too large a size. A ball of this kind has been known to lodge for a considerable time in the brain, the heart, or lungs. Fibrine is first effused around it, and, becoming organised, assumes the character of villous membrane, from which pus exudes, but which is rendered gradually thinner, puts on a smooth appearance, and at length secretes only a little serosity. Sometimes, however, the serous cyst accidentally inflames, an abscess forms, and fistulæ ensue, which continue as long as the cause of the irritation. According to the researches of Dupuytren, wherever balls lodge for a time and excite inflammation and suppuration, they are enveloped in a cyst, whose structure resembles that of a mucous membrane; and after a certain period, a communication is established between the cavity of the cyst and some point of the surface, or of the interior of the body. On the other hand, when a ball excites neither inflammation nor suppuration, the cyst presents an organisation exactly like that of a serous membrane, and contains between it and the ball a limpid serosity. (See *Dupuytren*, in *Clin. Chir.* t. ii. p. 432.) If, after extracting the ball from such a cyst, the wound be closed and healed by the first intention, a swelling is apt to form, composed of a collection of serous fluid in the cyst which is left. Hence, Dupuytren recommends either the removal of the cyst with the ball, or filling it with lint.

On account of the contusion which the parts suffer from the violent passage of the ball through them, a part of the textures surrounding the wound is most commonly deadened, and must afterwards be thrown off in the form of a slough. Hence, such wounds are generally prevented from healing by the first intention, and most of them necessarily suppurate. This does not take place equally in every gunshot wound, nor in every part of the same wound; and the difference commonly arises from the variety in the velocity of the body projected; for, where the ball has passed with little velocity, which is sometimes the case at its entrance, but still more frequently, at the part last wounded, the injury may sometimes be healed by the first intention. (*J. Hunter, Palmer's Edit.* p. 543.) [Several instances of wounds healing by the first intention, without suppuration, are recorded; in all probability, caused by bullets in rapid flight.]

M. H. Larrey, in his account of the gunshot wounds, which occurred at the siege of the citadel of Antwerp, has recorded several cases where the solutions of continuity were perfectly regular, and more or less like those made by a cutting instrument. Thus, one which was caused by the fragment of a shell, carried away a portion of the integuments of the chest, leaving a wound of a regular and elliptical shape, resembling that produced by an amputation of the breast. Its sides were brought together without sutures, and a cure was speedily accomplished. (See *Hist. Chir. du Siège de la Citadelle*

d'Anvers, p. 138.) [As a general rule, however, splinters from shell cause much laceration and are followed by sloughing and copious suppuration.]

Foreign bodies more frequently lodge in gunshot wounds than any others, and are commonly of three kinds. 1. Pieces of clothing, or other things, which the ball forced before it into the limb. 2. The ball itself. 3. Loose splinters of bone. It is only when the ball strikes the naked flesh, touches no bone, and goes quite through the part, that the wound can be free from extraneous matter. Foreign bodies are the cause of numerous unfavourable symptoms, by irritating sensible parts, and exciting pain, inflammation, spasms, hæmorrhage, long suppuration, &c.; and the more uneven, pointed, and hard they are, the more likely they are to produce these evils. Hence, spicula of bone are generally the most to be dreaded.

The great obliquity and length of the fissures, produced in the cylindrical bones by musket-balls, are such as are not remarked in any ordinary fractures. When I was with the army in Holland, in the year 1814, I had in the hospital at Oudenbosch, several fatal compound fractures of the thigh, caused by gunshot violence. The fissures in some of these examples were found to extend two-thirds of the length of the bone. This fact is noticed by Mr. Guthrie: "The fractures extend far above and below the immediate part struck by the ball, and, as far as depends upon my information from the examination of limbs that were amputated, farther downwards than upwards; so that, from a fracture in the middle of the thigh, I have often seen fissures extend into the condyles, and cause ulceration of the cartilages of the knee-joint," &c. (*On Gunshot Wounds*, p. 190.)

It is commonly stated that when a cannon-ball tears off a limb, it produces a violent concussion of the whole body, and a general derangement of all its functions. This, however, is by no means always true. I saw some years ago in London, a young sailor, whose arm had been completely torn off at the shoulder by a cannon-ball from one of the forts at Guadaloupe, in March, 1808: he suffered no dreadful concussion of his body, nor were his senses at all impaired. This case was very remarkable, as the scapula was so shattered, that Mr. Cumming of Antigua, was under the necessity of removing the whole of it. The patient recovered in two months. The axillary artery did not bleed.

[Like other injuries, gunshot wounds in unhealthy constitutions are not unfrequently followed by inflammation and deposition of pus in some internal viscus; more especially the lungs or liver; or sero-purulent effusion may take place into the cavity of the pleura; or the neighbouring cellular or muscular tissues may be the seat of these purulent deposits; or one or more of the joints may become inflamed, and purulent matter be infiltrated into them. The veins leading from the injury are found very generally to be thickened and to contain puriform matters. This unhealthy condition of parts sometimes commences very insidiously; but is generally accompanied with acceleration of the pulse, rigors, copious perspirations, and low typhoid symptoms. When these unfavourable occurrences follow amputation, they are preceded by an unhealthy aspect or sloughy state of the stump. For further information on this point see the article PYÆMIA.]

From the circumstance of the inner surface of gunshot wounds being often more or less deadened, they are late in inflaming. This explanation of the fact, as delivered by John Hunter, is the best yet offered. Traumatic inflammation being at first generally indolent, gives to gunshot wounds, in their first stage, as Dupuytren observes, a deceitful appearance of mildness (see *Clin. Chir.* t. ii. p. 452); for afterwards, the inflammation, which is often more considerable at the entrance than the exit of the ball, becomes very intense. But when a ball has fractured a bone, which fracture has occasioned great injury of the soft parts, independently of that caused immediately by the ball itself, the inflammation will come on as quickly as in cases of compound fracture; because the deadened part bears no proportion to the laceration or wound in general. (*J. Hunter, Palmer's Edit.* p. 543.)

From the same circumstance of a part being often deadened, gunshot wounds frequently cannot be completely understood in the first instance; for, in many cases, it is at first impossible to know what parts are killed, whether bone, tendon, or soft part. Nor can this be ascertained till the slough separates, which often makes the wound much more complicated than was previously imagined. For some viscus or a part of some viscus, or a part of some large artery, or even a bone, may have been killed by the violence. If a piece of the intestine has been killed, the contents of the bowel will begin to come through the wound when the slough separates. If a portion of a large blood-vessel is killed, a profuse, and even fatal hæmorrhage may come on, when the slough is detached, although no material quantity of blood may have been previously lost. (See *Hunter, Palmer's Edit.* p. 544.) Thus several days after the receipt of the wound, and when all danger from inflammation is over, a bleeding *per anum*, occasioned by the separation of a slough from some internal vessel, may destroy the patient, as happened in a very interesting case reported by Mr. Guthrie. (p. 13. ed. 2.) A soldier of the 2nd battalion of the 44th regiment was shot in the ham at the assault of Bergen-op-zoom, in 1814. There was no hæmorrhage for ten days; but at the end of this period, the popliteal artery gave way, and I was obliged to take up the femoral artery, by which means the bleeding was effectually stopped, and the man recovered.

When the ball moves with little velocity the mischief is generally less, the bones are not so likely to be fractured, the parts are less deadened, &c. However, when the velocity is just great enough to splinter a bone which is touched, the splintering is generally more extensive than if the impetus of the ball had been much greater, in which case a piece is more likely to be taken out. When the ball moves slowly, it is more likely to be turned by any resistance it may encounter in its passage through parts, and hence the wound is more apt to take a winding course.

The track of a ball is generally more or less tortuous in consequence of the unequal resistance of the different textures and the deviations of the projectile itself.

When a ball enters a part with great velocity, but is almost spent before it comes out again, in consequence of the resistance it has met with, there may be a good deal of sloughing about the entrance, and little or none about the exit, owing to

the different degrees of celerity with which the ball traversed the parts. (See *Hunter, On Inflammation, Gunshot Wounds, &c.*)

The effects of a ball upon a bone vary according to circumstances. Sometimes they only amount to a contusion of it; but this accident, though slight in appearance, is frequently followed by perilous consequences. The periosteum, if not destroyed, inflames and separates from the bone, and necrosis ensues to a greater or lesser extent. If the bone be of a spongy texture, the inflammation may spread far in its internal vascular structure. In the skull the two tables are almost always attacked by necrosis, and the dura mater inflames consecutively. If the force of the projectile be such as to overcome the resistance of the bones, these are broken with greater facility in proportion as their hardness is more considerable and their elasticity less. The flat bones, like those of the cranium and the scapula, are sometimes perforated as cleanly as if a portion of them had been taken out with a circular saw. In other instances they are more extensively broken and comminuted. A ball may break a part of a long bone, like the tibia, without a fracture being produced, extending through all its circumference; but more commonly, the middle compact portions of the long bones are reduced into numerous fragments of various shapes and dimensions. If the projectile retains but very little impetus, or strikes a bone obliquely, this may be fractured without being at all splintered. Of this, two instances are recorded by Dupuytren. (*Clin. Chir.* t. ii. p. 442.)

Gunshot wounds may have either one or two apertures, according as the ball has lodged or passed quite through the part. In some cases the openings are diametrically opposite each other; in others they are not so, the direction of the ball having been changed by the resistance which it met with from a bone, cartilage, tendon, &c. Thus a ball has been known to enter just on the inside of the ankle and come out near the knee, to enter the forehead and come out at the temple, &c. (*Richerand, Nosographie Chir.* t. i. p. 219, edit. 2.) Dr. Hennen mentions an instance in which a ball entered near the pomum Adami, and after running completely round the neck, was found in the very orifice at which it had entered. "This circuitous route is a very frequent occurrence, particularly when balls strike the ribs or abdominal muscles, for they are turned from the direct line by a very slight resistance indeed, although they will at times run along a continued surface, as the length of a bone along a muscle or a fascia, to a very extraordinary distance." Dr. Hennen refers to cases in which the ball traversed almost the whole extent of the body and extremities. "In one instance, which occurred in a soldier, with his arm extended in the act of endeavouring to climb up a scaling-ladder, a ball, which entered about the centre of the humerus, passed along the limb, and over the posterior part of the thorax, coursed among the abdominal muscles, dipped deep through the glutæi, and presented on the forepart of the opposite thigh, about midway down. In another case, a ball, which struck the breast of a man standing erect in the ranks, lodged in the scrotum." (*Principles of Military Surgery*, p. 34. ed. 3.) Le Vacher saw a case in which a ball entered the front of the thigh, and came out at the point diametrically opposite, without the femur being broken. Facts of this

description are all capable of explanation, by reference to the laws of projectiles.

[The foregoing remarks apply to wounds made by the spherical bullet. The conical balls used so extensively in the Crimean and more recent campaigns, inflict a much more severe and dangerous wound than the old round bullet. "Usually they admitted of being very little deflected from their course, piercing bones and generally perforating the limb, sometimes even wounding several men. Conical bullets, from their wedge-like action, have the peculiar tendency to produce longitudinal fractures of the bones of the extremities of very considerable extent; sometimes, indeed, running through the whole length of a bone. The greater weight of the conical bullet was partly a cause of its increased power of injury.

"The conical bullets of the Russians differed considerably from either the old Minié ball with the iron cap, or the Enfield rifle bullet of the British army. They used three forms. The heaviest and largest weighed 840 grains, and was a solid mass of lead with three flanges near the flat base and tapering to a sharp apex. The second was less weighty and without flanges, but had a hollow in the base to admit of its expansion. The third had neither flange nor hollow at the base. All were considerably heavier than the Enfield rifle bullet which only weighs 580 grains. Of all these bullets, the worst and most dangerous wounds appeared to be inflicted by the British old-fashioned Minié bullet with the iron cap. The cap sometimes had the effect of splaying out the ball on its encountering an obstacle, and thus much increasing the extent of the parts brought into direct contact with the missile. Next in destructive power would appear to be the largest Russian ball, but this, the Enfield rifle ball, and the two other varieties of conical ball above mentioned, differed but little in this particular. When these bullets came in contact with the shaft of a long bone, they generally produced a compound comminuted fracture of a very serious nature. In the case of the femur, the comminution was very generally so extensive as to render amputation necessary. The round balls much more frequently lodged, and the fractures of long bones produced by them were usually much less comminuted and less extensively split than by the conical bullet." (*Medical and Surgical History of British Army in the Crimea.*)]

Dupuytren observes, nothing is more diversified and extraordinary than the course of projectiles amidst the textures of the body. In 1830, a combatant, on the *Pont d'Arcole*, was struck by a ball, which entered at the internal angle of the left eye; and the wound, which took a direction backwards, and rather to the right, seemed as if it had gone quite through the head. However, the ball, after passing below the cranium, made its exit above the right shoulder. The man soon recovered, without any dangerous symptoms. Another man was wounded in the head, on the *Pont Notre Dame*; the ball went through his hat, travelled along the right side of the nose, penetrated the upper lip, broke four of the upper teeth, fractured the lower jaw, came out behind the chin, entered again at the root of the neck behind the clavicle, and lodged in the cushion of the left shoulder. This patient died of inflammation of the chest. (See *Clin. Chir.* t. ii. p. 448.)

When there is only one opening, we may infer

that the wound contains a foreign body. An exception to this observation occurs, however, when a ball, instead of tearing the clothes, or linen, carries a portion of them, in the form of a pouch, into the wound, and, when such portion of the clothes is withdrawn, the ball falls out; and if this circumstance be not noticed, the presence of a single opening may lead to the idea that the bullet is lodged in the part. An instance of this kind is cited by Paré, for the purpose of refuting the former notion, that the ball burnt the parts. A case, in which a piece of a shirt was carried in this manner four inches into the flesh, is mentioned by Mr. Guthrie. (p. 4. ed. 6.) [A deep hole may be made in the soft parts and bone by the projecting angle of a fragment of shell without its remaining in the wound, and lead to the supposition that it was caused by a bullet which has become lodged in the part. An instance of this occurred before Sebastopol in the shaft of the tibia.]

In 1814, a French soldier, wounded under the walls of Paris, was brought to the Hôtel-Dieu. On examining the upper part of the leg, Dupuytren found some cloth forced into the tibia; and on pulling it out, which required considerable effort, a ball was extracted, completely enveloped in a piece of gaiter. Amongst the wounded brought into La Pitié, in July, 1830, was one case in which a ball had penetrated the abdomen, propelling before it a portion of the shirt which was not torn, and served very usefully to facilitate the extraction of the projectile. (See *Dupuytren*, in *Clin. Chir.* t. ii. p. 426.) It is possible also for a ball to be stopped immediately it has entered the body, and then to be ejected by the elasticity of the parts against which it strikes, as the cartilages of the ribs. (*Guthrie*, p. 5, ed. 6.)

When there are two apertures made by one shot, the ball, or at all events a portion of it, has escaped; but pieces of the clothes, &c. may still be lodged in the part. Care must be taken, however, not to confound with these cases others, in which the plurality of openings has been made by different balls.

"It is no uncommon thing (observes Dr. J. Thomson) for a ball, in striking against the sharp edge of a bone, to be split into two pieces, each of which takes a different direction. Sometimes it happens that one of the pieces remains in the place which it struck, while the other continues its course through the body. Of a ball split by the edge of the patella, I have known one half pass through at the moment of the injury, and the other remain in the joint for months, without its presence there being suspected. In the same manner, I have known a ball divided by striking against the spine of the scapula, and one portion of it pass directly through the chest from the point of impulse, while the other moved along the integuments till it reached the elbow-joint. But the most frequent examples of the division of bullets, which we had occasion to see, were those which were produced by balls striking against the spherical surface of the cranium. It sometimes happens that one portion of the ball enters the cranium, while the other either remains without, or passes over its external surface. [Or, a ball may be split against the edge of a fracture in the cranium, and one portion enter without leaving an opening, the depressed portion of bone rising into its place again. An interesting example

of this occurred in the 19th regiment, before Sebastopol.]

"Not unfrequently, in injuries of the cranium the balls are lodged between its two tables, in some instances much flattened and altered in their shape, and in other instances, without their form being changed." From these facts it must be evident that even when a gunshot wound has two orifices the surgeon cannot be certain that the bullet has not been divided, and that no portion is lodged, unless the entire ball itself happen to be found. (See *Thomson's Obs. in Military Hospitals in Belgium*, p. 37, &c.) This part of the subject is noticed by all the best practical writers, and especially by Barons Larrey and Dupuytren. When a ball strikes against hard substances, it is liable, says Dupuytren, to be changed in its shape, flattened, or broken into fragments, so as to produce injuries not readily accounted for. Thus, in one case mentioned by him, the ball struck against the sharp edge of the right tibia, and was split into two pieces, each of which passed through the calf of that limb, and then lodged in the calf of the other. Thus five openings were made by a single ball. (*Dupuytren, Clin. Chir. t. ii. p. 428.*) In July 1830, a Swiss soldier was brought into the Hôtel-Dieu, wounded by a ball, which had fractured the right parietal bone, and been split into two pieces, one of which escaped through the scalp, whilst the other passed through the posterior lobe of the brain, and lodged upon the tentorium. About the same period, another individual was admitted into the same hospital, with the occiput fractured, by a ball which was split, but fixed with the margin of the bone in its cleft. (*Dupuytren, Clin. Chir. t. ii. p. 444.*) A single ball, though not split, may produce several openings. M. H. Larrey mentions a case in which a ball passed through the hand, then the skin of the groin, and next the left buttock, so as to cause six openings. (See *Hist. Chir. du Siège d'Anvers*, p. 67.) Mr. Guthrie once spoke to me of another instance, in which six openings were left by a single ball, that passed through both thighs and the scrotum.

As the ends of the vessels are contused and torn, gunshot wounds have generally at first little propensity to bleed seriously, unless vessels of importance happen to be injured. In the beginning there may even be little hæmorrhage; though a considerable artery be so hurt that it afterwards sloughs, and a dangerous or fatal bleeding arises. Thus (as I have already mentioned), in one of my own patients, who had received a musket-ball through the ham, the popliteal artery gave way about ten days after the injury, and compelled me to take up the femoral artery; and in the Elizabeth Hospital at Brussels, amongst the patients under the care of my friend Mr. Collier and myself, about a week after the battle of Waterloo, the cases of hæmorrhage on the loosening of the sloughs were numerous, not at all coinciding with a calculation that the proportion of such examples, requiring the ligature of arteries, is only three or four in a thousand. (*Guthrie on Gunshot Wounds*, p. 2, ed. 6.) In Holland the truth of Mr. Hunter's observation upon this point appeared to me to be completely confirmed.

It has long been known that a limb may be torn or shot off, even near to the trunk of the body, and hardly any hæmorrhage arise. We had numerous

proofs of this fact after the battle of Waterloo. I had under my care a man of the rifle brigade, whose arm was shattered to pieces as high as the shoulder, yet there was no hæmorrhage. I amputated the thigh of a Dutch soldier, whose leg had been completely shot off by a cannon-ball; but there was no hæmorrhage before the operation. At Merksam, in 1814, I saw a case in which the greater part of the clavicle, scapula, and many adjacent parts had been carried away by a cannon-ball, and yet no bleeding of consequence occurred. The reason why a gunshot wound sometimes does not bleed much, though an artery of magnitude is torn, is because the vessel is nearly in the same state as when torsion has been practised; that is to say, the end of it has been violently stretched, so as to draw out the elastic external coat from the inner ones, which remain in the form of irregular folds within the mouth of the artery, constituting a kind of barrier against the escape of the blood. But if the artery be only partly torn through, this change is not sufficiently complete, and a profuse and fatal hæmorrhage may immediately follow the wound. The clot that forms within the vessel, is also an additional obstacle to the bleeding.

Sometimes, after a limb has been shot off, the large arteries do not bleed in amputation. "We saw a man (says Dr. Thomson), whose leg had been shot off by a cannon-ball; in amputating his limb above the knee, the arteries of the thigh were not perceived to bleed, nor did any of them afterwards require to be tied. A case, similar to this, also presented itself, in which the arm had been shot away close to the shoulder-joint."

Sometimes the contusion produced by a cannon-ball, or the passage of a bullet in the vicinity of a large artery, seems to cause a laceration of the inner coat of the vessel, and a subsequent obliteration of its cavity by the effusion of coagulable lymph. Facts in proof of this statement are recorded by Dr. Thomson. (See *Obs. in the Military Hospitals in Belgium*, p. 34, 35.)

In general, the most dangerous kind of hæmorrhage from gunshot wounds is that named *consecutive* or *secondary*. Either the artery has been totally or partially divided. In the first case, the slough immediately produced by the ball, the clot, which forms in the cavity of the vessel up to the first collateral branch, and (as I should add) the irregular folds of the inner coats, detached from the outer, put a stop to the bleeding. But frequently, as soon as the circulation acquires strength, these impediments are overcome, and hæmorrhage comes on. In other cases they continue to be efficient until the whole internal surface of the wound, and the lacerated and disorganised part of the artery are detached and loosened, as suppuration advances. But in this stage, if the end of the obliterated artery is too short, if the adhesive process is incomplete, or the patient moves about too much, the artery will give way. As Dupuytren observes, it is most commonly about the tenth, fifteenth, or even as late as the twentieth day, that these secondary hæmorrhages happen, without any particular symptom to give warning of their occurrence, excepting a thin bloody serosity, which is sometimes discharged from the wound. Hence the necessity for the utmost vigilance at the period when such bleedings are to be expected. They are infinitely more

perilous than primary hæmorrhages, both on account of the patient's weakened state, and the condition of the arteries and surrounding textures, occasioned by the inflammation. In cases of primary hæmorrhage, the artery may be readily distinguished, taken hold of, and tied; and the ligature does not separate before the expiration of several days, when the process of obliteration has been insured. But in secondary hæmorrhages, circumstances are different. The tissues are retracted and converted into a compact mass, and the vessel, which can hardly be discerned, is easily cut through by the ligature, or at all events, the latter falls off before the obliteration has acquired adequate strength. Hence bleeding frequently comes on again in the course of a few hours. In cases of this description, Dupuytren observes, there is no other resource but that of taking up the trunk of the artery at a greater or lesser distance from the accidental opening in it. (See *Clin. Chir.* t. ii. p. 465.)

Still later forms of secondary hæmorrhage occur in gunshot wounds, complicated with hospital gangrene, or bad compound fractures, which have been in the suppurative stage for weeks or months. In these last examples even small arteries may pour out at once, or by repetition, a quantity of blood, sufficient to bring the debilitated patient quickly to the grave. The blood does not issue from one individual vessel, but from the whole surface of the wound as from a sponge, and is so thin as to resemble blood and water.

Gunshot wounds, particularly those of the limbs, are frequently complicated with broken bones, which are a principal source of danger. The bones are seldom fractured merely in one place, but almost always splintered into numerous irregular pieces, which the violence of the shock often separates from the rest of the bone, and forces into the surrounding soft parts. If to such mischief be added that which the soft textures experience from the direct action of the projectile itself, the laceration of muscles, tendons, fascia, nerves, and blood-vessels, there will be exemplified, as Baron Dupuytren justly remarks, a combination of everything bad which a complicated fracture can be attended with. In no situation is the danger greater than in the leg and thigh; in the former, on account of the thickness of the muscles and fasciæ; in the latter, on account of the number and size of the bones. The immediate consequence of the fracture, and the presence of splinters, is a violent inflammation, commencing in the broken part, and propagating itself to the whole limb. The textures, most seriously contused, are frequently seized with gangrene; and after the sloughs have been detached, extensive portions of bone are left exposed. This is very often noticed in fractures of the leg. The suppuration becomes profuse; the fragments of bone lie inundated in pus, and becoming denuded, lose their vitality; and the pus itself passes by long sinuses between the layers of muscles, and along the surface of the bone, to a vast distance. If a fragment of bone lie near an artery, its pressure will sometimes cause ulceration of the vessel and a very late form of secondary hæmorrhage. This danger is principally observed in the leg and thigh. M. Pelletan relates a case in which the bleeding from this cause took place as late as the seventieth day. (See *Dupuytren, Clin. Chir.* t. ii. p. 455.)

TREATMENT OF GUNSHOT WOUNDS.

When the case is merely one of *contusion* without wound, or disorganisation of textures, the surgeon may sometimes keep the inflammation within due bounds. The cure may then be accomplished without any solution of continuity in the skin taking place. But more commonly, as Dupuytren observes, acute inflammation comes on, the parts are rapidly seized with gangrene, and if the mischief be extensive, death is almost sure to follow. Textures, whose organisation has been too much injured by contusion, cannot bear inflammation. The mortification sometimes reaches further than first appearances enable us to foresee, and it is only now that the alarming nature of the case is manifest. As for *wounds*, whether they implicate only the soft parts, or the bones also, they are of a kind which in general must unavoidably suppurate; but the prospect of cure will be greater in proportion as their depth is less, as they are free from foreign bodies, and the general condition of the patient is satisfactory. (See *Dupuytren, Clin. Chir.* t. ii. p. 451.)

[The first point to decide upon when called to undertake the treatment of a gunshot wound of a limb, is to determine whether it be most advisable to amputate immediately or to defer it; to excise the broken portions of bone, reserving the limb, or to attempt the cure of the injury without operation.] When a bone, especially at a joint, is very much shattered; when the fleshy parts, particularly the great blood-vessels and nerves, are lacerated; when the whole limb has suffered a violent concussion, and is cold and senseless, there is no hope of preserving it. In this case it is the surgeon's duty to amputate at once, and not to delay till inflammation, fever, and mortification set in. But, besides this violent degree of injury, in which the propriety of amputation is obvious, several lower degrees occur, in which it is often a difficult thing to decide whether the operation be necessary or not. Here the surgeon must look not only to the injury, but also to the patient's constitution, and even to external circumstances, such as the possibility or impossibility of procuring good accommodation, rest, attendance, and pure air. But it is impossible to determine the necessity of amputation by general rules. In every individual case the surgeon must consider maturely the particular circumstances before he ventures to decide. The grounds against the operation are the privation of a limb, and frequent examples in which nature, aided by judicious surgery, repairs the most horrible wounds. The following are the reasons in favour of the operation. By it the patient gets rid of a dreadful contused wound, which threatens the greatest peril, and which is exchanged, as it were, for a simple incised one. In cases of gunshot wounds, the loss of the limb cannot be taken into the account; for the surgeon only undertakes the operation where he designs to save the patient's life by that privation, and anticipates that the part itself cannot be preserved. Even if he should deprive the patient of a limb that perhaps might have been preserved, there is this atonement,—that he can furnish him with an artificial leg, which often proves far more serviceable than the limb would have proved had it been preserved. Should the operation be fixed on, it is to be immediately performed above the wound. (*Richter.*)

[When neither amputation nor excision is deemed necessary, the wound should be cleansed, and all foreign bodies within reach, and removable, should be extracted, especially such as press on parts of importance. If there are any detached spicula of bone, these should all be carefully withdrawn. Dilatation and enlargement of the wound are to be avoided if possible, as recommended by Mr. Hunter, Hennen, Thomson, and Guthrie.] In these cases where the extraneous bodies are more deeply and firmly lodged in the wound, the surgeon should await suppuration and the detachment of sloughs; and when the foreign bodies become moveable and apparent, he should extract them, with or without an incision, as circumstances may demand. The examination of the wound ought to be made as much as possible with the finger, which irritates less, and feels more distinctly than a probe. A great variety of instruments have been devised, either for ascertaining the position of balls and other foreign bodies in gunshot wounds, or for extracting them. But, however numerous and diversified bullet-drawers may be, they all admit of being divided into three kinds. The first are constructed on the principle of a pair of forceps; others are shaped more or less like spoons; and a third description are made on the plan of a cork-screw or worm. These last are only designed for cases in which the ball is fixed in the substance of a bone, and is quite immovable; for, if it were lodged in the soft parts, the pressure requisite for introducing the screw into it would injure and lacerate the parts at the bottom of the wound. Bullet-drawers constructed on the plan of forceps have the inconvenience of not being adapted for seizing the ball, unless their blades can expand, which always stretches the wound and creates a great deal of irritation. Forceps have been contrived with blades, which may be introduced separately, and then joined together with a screw. When a ball lies superficially, the fingers, or a small pair of forceps, will extract it most conveniently. And, with respect to bullet-extractors, as Dr. Hennen has justly observed, they are completely superseded by the common forceps, or that of Baron Percy, though unfortunately the aid of instruments is most required in tortuous deep passages, where we can least make use of them. (*Principles of Military Surgery*, p. 76, ed. 3.)

[These instruments are but little in favour with most military surgeons; they are seldom used and but little required, except for the extraction of deeply-seated bullets. The best form is that where the blades can be introduced separately, and afterwards made to lock into each other like the midwifery forceps; an instrument of this kind has been constructed by Mr. Blaise, which, with slight curvature in the blades, would answer their purpose very well.]

The event of the treatment above recommended, is various. Extraneous substances remaining in the wound, either loosen gradually, and come into view, so as to be easily removeable; or they continue concealed, prevent the cure, and give birth to a fistulous ulcer. In some instances the wound closes, and the foreign bodies remain in the limb during life without inconvenience; and in other cases, after a time, they bring on a renewal of inflammation and suppuration. Sometimes a foreign body varies its situation, sinking down, and afterwards making its appearance at a different

part, where it may excite inflammation and suppuration. It may change its place slowly, or quickly; when quickly, it leaves no trace of its passage in the textures which it travels through; when slowly, it becomes enveloped in a serous cyst. This disposition to change of place appertains not only to sharp, smooth, oblong bodies, but also to globular ones; though it is generally less in proportion, as they have more of the spherical shape. As Dupuytren observes, these facts should not be lost sight of by the surgeon; for it often happens that a foreign body, which is distinctly felt on one day at a certain point, may be very far from it on the next. Hence, incisions for the extraction of a ball are never to be made but from the information acquired respecting its situation. (See *Dupuytren, Clin. Chir.* t. ii. p. 434.)

When the ball lodges in the wound, it is usually difficult to trace it, as the parts collapse after its passage, and leave an opening in the skin much smaller than the ball itself. The ball does not regularly take a straight direction through the injured part, but often a very tortuous one, particularly when the ball is nearly spent. In every case in which it is not easily discoverable, all painful examinations should be abandoned, and the foreign body left in its situation until its place is better known, and the first inflammation is over.

[When a ball nearly traverses a limb and lodges under the skin of the opposite side, and can be readily felt, it should be cut down upon and removed, as no inconvenience ensues.] But when the ball lies three or four inches from the surface, and cannot be distinctly felt, no incision should at first be made with the view of extracting it. (*On Gunshot Wounds*, p. xii. ed. 6.)

Sometimes the ball penetrates the spongy part of a bone and lodges firmly in it. When it has only entered superficially, it may sometimes be loosened and extracted by means of an elevator, with a thin and somewhat curved extremity; and when it is more firmly fixed, a screw bullet-drawer will sometimes serve for its removal. Should the attempt fail, the employment of a trephine for the removal of the ball is recommended by some writers; while others, fearful of the irritation, difficulty, and effects of such an operation, and recollecting that balls have sometimes remained fixed in bones for many years, without any serious inconvenience, condemn that practice. On the contrary, Mr. Guthrie lays it down as a general rule, subject to a few exceptions, that a ball should never be allowed to remain in a bone; for, says he, "if a ball lodge in the head of a bone, and is not removed, it generally causes caries of the bone, disease of the joint, amputation, or death. If in the shaft of a long bone, necrosis for the most part follows, with months and years of misery. On a flat bone, caries is equally the result, and if it be surrounded by large muscles, sinuses form in various directions, contractions of the limb take place, and the patient drags on for years, careless of life, and ready to submit to anything to obtain relief. (*On Gunshot Wounds*, p. 144, ed. 6.) In many of these cases, one thing deserves to be recollected, however, that the necrosis, abscesses, and sinuses are less the effect of the lodgment of the ball, than of the violence originally committed on the parts against which it has struck. Although Baron Larrey only sanctions the attempt to remove balls with a

trephine, when they actually produce dangerous effects (*Mém. de Chir. Mil.* t. iv. p. 185), I am disposed to believe, that whenever the situation of the ball is such that it can be removed at once from a bone with tolerable certainty, and without too much irritation, the practice is commendable.

As soon as the requisite incisions have been made, and foreign bodies extracted, the prime objects in the treatment of gunshot wounds are accomplished; and the rest is, in reality, not different from the surgery of other wounds.

With regard to probing gunshot wounds, when it is evident that the shot has passed out, and no particular object can be fulfilled with the probe, it is often better to dispense with such examination, at least till suppuration has come on. The needless use of a probe causes unnecessary pain and irritation. But when the ball, or any other extraneous substance, has lodged in the wound, and its situation is not immediately evident, it will often be advisable to search for it at once, in order that it may be extracted, if its situation will allow, before inflammation begins. The surgeon, therefore, considering all the circumstances which can assist him in forming a reasonable conjecture of the course of the wound, must give to a probe that curvature, or form, which he thinks most likely to pass readily along it, and must then proceed to make the examination. But when this is very painful, and the course of the wound obscure, it will often be better to desist, and renew the search when suppuration has taken place, in which stage it can be undertaken with more ease, and a greater prospect of success. When gunshot wounds are inflamed, the tenderness and swelling of the parts are peculiarly strong reasons against painful probings, or efforts to extract foreign bodies, as long as this state lasts. (See *Chevalier on Gunshot Wounds*, p. 67, 68. ed. 3.)

[The external means of treatment applied to gunshot wounds in the present day are as simple as possible. A piece of linen or lint moistened with warm or cold water, and covered with oil silk or gutta percha tissue, and retained on the part by a fold or two of linen bandage lightly applied, is all that is necessary. I never used any other in any of the cases that I had occasion to treat before Sebastopol, and I never had any reason to regret the practice. Ointments, pledgets of lint, adhesive plasters, are all generally unnecessary. When suppuration has been established, a bread poultice may be then usefully substituted, and should the discharge be fetid and the surface of the wound or stump foul, pulverised charcoal should be sprinkled over it. A yeast or carrot poultice is a good application in such condition of wounds; but these cannot be always obtained on the field. The poultices should be frequently renewed. When the discharge has diminished, and the surface of the wound or stump has assumed a healthy character, the cold water dressing is to be re-applied and the poultice discontinued. One has rarely to have recourse to strong antiphlogistic measures in these injuries; but they must be resorted to if necessary, as in other wounds. Care, however, should be taken that the patient's strength is not too much reduced, lest it be inadequate to support the very frequently copious and long-continued suppuration which often ensues upon these wounds.]

Gunshot wounds, in crowded military hospitals, especially when they are established in unhealthy, low, damp situations, and due attention is not paid

to ventilation and cleanliness, are liable to be attacked by hospital gangrene, a most serious and dangerous complication. (See HOSPITAL GANGRENE.) Another formidable and generally fatal complication, is traumatic tetanus. (See TETANUS.) A third dangerous complication is *erysipelas*, particularly the phlegmonous kind.

For a few days, the matter seldom assumes a healthy appearance; but as soon as the sloughs separate, it then becomes of a proper quality, and is to be treated as an ordinary wound. As Dupuytren remarks, when the patient has got through all the dangers of the earlier stages of gunshot wounds, hæmorrhage, gangrene, phlegmonous erysipelas, tetanus, and other perils, still await him. The fractured bones unite with difficulty; sinuses and deep abscesses form in the limb; the periosteum becomes detached; the bones denuded; and attacked by necrosis. Nor is this all the mischief: fractures of bones abounding in spongy texture are liable to be complicated with inflammation of the cellulo-vascular membrane, investing the areolæ of that texture, and its numerous veins. This inflammation, which is always followed by necrosis, sometimes extends a great distance, and this more especially in cases where the ball has occasioned a violent concussion of the bone.

Sometimes the healing process does not commence, though suppuration has prevailed a considerable time. On the contrary, notwithstanding the exhibition of tonics, and a generous diet, the suppuration ceases to proceed favourably, and the wound becomes unhealthy and the matter thin. The bones show no disposition to unite, and the patient, reduced by hectic symptoms, is rapidly approaching dissolution. In this state, life may sometimes be preserved by amputation.

OF AMPUTATION IN GUNSHOT WOUNDS.

The second edition of this Dictionary, published in 1813, contained all the valuable observations of Baron Larrey in favour of *immediate* amputation, in every instance in which the operation is considered indispensable. Since then, the public have been favoured with several good practical books, in which the propriety and necessity of early or immediate amputation in such cases are urgently inculcated, and the truth of the doctrine is illustrated by additional facts. It is to be observed, however, that for the last two hundred years, there have always been some advocates for this judicious practice. "Du Chesne (says Dr. J. Thomson) is the first writer on military surgery in whose works I have found the recommendation to amputate in the severer injuries of the extremities; and it is worthy of remark, that he directs the operation to be performed before inflammation and other constitutional symptoms shall have supervened." (See *Traité de la Cure générale et particulière des Arcbusades*, par Jos. Du Chesne, Paris, 1624, p. 143; and Thomson's *Report*, &c., p. 160.) Wiseman not only recommended and practised immediate amputation, but the same thing was not unfrequently done by the military surgeons of his time. (*Chirurgical Treatises*, by R. Wiseman, 3d ed. Lond. 1696, p. 410.) The celebrated Le Dran, in his excellent little manual of military surgery, declared himself an advocate for *immediate* amputation, in all cases in which that operation from the first appears to be indispensable. Le Dran has, at the same time

stated briefly, but most distinctly, the comparative advantages of that practice, with those which may be expected by delay. (See *Traité, ou Réflexions tirées de la Pratique sur les Plaies d'Armes à feu*, par H. F. Le Dran, à Paris, 1737.) Ranby, who was serjeant-surgeon to King George II., entertained similar opinions to those of Le Dran, with regard to the utility of immediate amputation. In order to give immediate relief to the wounded, and to facilitate the performance of the necessary operations, Ranby proposed that the surgeons, during battle, should be collected into small bodies, and stationed in the rear of the army. (See *The Method of treating Gunshot Wounds*, by John Ranby, ed. 3. p. 29. Lond. 1781.) Schmucker, who was many years surgeon-general to the Prussian armies, published in 1776 an essay on amputation, in which he particularly mentions that, during his stay at Paris, in 1738, the surgeons of the Hôtel-Dieu had been in the habit of performing immediate amputation in severe injuries of the extremities. *He also declares himself an advocate for operating immediately in all cases in which amputation from the first appears to be necessary*, and insists, in a particular manner, on the increased danger which he had seen arise from the operation during the second period. He gives (as Dr. J. Thomson has observed) a minute and circumstantial enumeration of those injuries, both of the upper and lower extremities, in which he conceived amputation to be necessary, and in many of which he had actually performed it with great success. Schmucker appears to Dr. Thomson to have given a better account than any preceding military surgeon, of the injuries of the thigh; and from the results of his experience, he was led to believe that, *though compound fractures of the lower part of the thigh-bone might, in favourable circumstances, be cured, without amputation, yet that this operation is peculiarly necessary in all cases in which the fracture is situated in or above the middle of that bone.* (J. L. Schmucker, *Vermischte Chirurgische Schriften*, b. i. Berlin, 1785.) With the foregoing high authority we have to join one of not less celebrity, namely, that of Baron Larrey, who has proved most convincingly, that when amputation is to be done in cases of gunshot wounds, nothing is so pernicious as delay. (See *Mém. de Chir. Mil.* t. ii. p. 451, &c.)

The principles inculcated by Baron Larrey are, in point of fact, the same as those which were so strenuously insisted upon by Pott, whose principal remarks on the necessity of amputation in certain cases are detailed in another part of this publication. (See AMPUTATION.) Pott, indeed, was not an army-surgeon, and what he says was not particularly designed to apply to military practice: but he has represented, as well as any body can do, the propriety of immediate amputation for injuries which leave no doubt that such operation cannot be dispensed with.

Mr. John Bell, amongst the moderns, appears likewise to have much merit for the able manner in which he defended the propriety of early amputation, long before the sentiments of later writers were ever heard of. He distinctly states that "amputation should, in those cases where the limb is plainly and irrecoverably disordered, be performed upon the spot." (See *Discourses on the Nature, &c., of Wounds*, p. 488. edit. 3.) In short, notwithstanding all the modern pretensions

to novelty upon this interesting topic, we must acknowledge, with Dr. Thomson, that the evidence in favour of the advantages of immediate amputation has always preponderated over that for delay. (See *Report of Obs. &c.* p. 225.)

The strongest body of evidence upon this matter is undoubtedly adduced by Baron Larrey, whose situation at the head of the surgical department of the French armies afforded him most numerous opportunities of judging from actual experience. "Upon this subject (says he), now that twenty years of continual war have carried our art to the highest pitch of perfection, there can only be one opinion. It is after having incessantly directed the medical service all this time, in the quality of head-surgeon and inspector-general of the armies, that I proceed to discuss the different opinions delivered in the Academy, and to settle definitely this great question, which I regard as the most important in military surgery.

"If we are to be told that the amputation of a limb is a cruel operation, dangerous in its consequences, and always grievous for the patient, who is thereby mutilated; that, consequently, there is more honour in saving a limb than in cutting it off with dexterity and success; these arguments may be refuted by answering that amputation is an operation of necessity which offers a chance of preservation to the unfortunate, whose death appears certain under any other treatment; and that, if any doubt should exist of amputation being absolutely indispensable to the patient's safety, the operation is to be deferred till nature has declared herself, and given a positive indication for it. We are also justified in adding that this chance of preservation is at the present day much greater than at the epoch of the Academy of Surgery. We learn from M. Faure that of about three hundred amputations performed after the battle of Fontenoy, only thirty were followed by success, whilst on the contrary (says Baron Larrey) we have saved more than three-fourths of the patients on whom amputation has been done, and some of whom also had two limbs removed." This improvement is ascribed by Larrey, 1. To our now knowing better how to take advantage of the indication and favourable time for amputating. 2. To the better method of dressing. 3. To the mode of operating being more simple, less painful, and more expeditious than that formerly in vogue.

To the preceding authorities against delaying amputation in cases of gunshot wounds requiring such operation, I have to add Mr. Guthrie, whose opportunities of observation during the late war in Spain were particularly extensive. In his work he has detailed the opinions of many eminent foreign and British surgeons respecting the propriety or impropriety of the doctrine of immediate amputation, and he has introduced some good criticisms particularly on Bilguer's statement of the success which was experienced in the Prussian hospitals from not performing the operation. Mr. Guthrie, however, does not recommend amputation to be done immediately, if the patient be particularly depressed by the shock of the injury directly after its receipt; a piece of advice which I believe has, in reality, been at all times followed, not only in respect to amputations in cases of gunshot wounds, but all other severe local injuries. "I believe it to be (says Mr. Guthrie), a stretch of fancy in those surgeons who conceive that if the knife followed the shot in

all cases the patient would have the best chance of success. No one will deny that if the shot performed a regular amputation, it would not be better than to have to do it afterwards: but if they mean to say the operation should in general be performed immediately after the injury, I can only oppose to them the facts above stated, and the general results of my experience, which is decidedly in favour of allowing the first *moments* of agitation to pass over before anything be done; a period extending from that to one, six, or eight hours, according to the difference of constitution and the different injuries that have been sustained. But, *from one to three hours* will, in most cases, be found sufficient." (*Commentaries on the Surgery of the War*, 6th ed. p. 41.)

So far as my experience goes, when the necessity of amputation is undoubted, all delay is improper beyond the short period during which the faintness immediately arising from the injury usually lasts. In the campaign in Holland, 1814, the most successful amputations were those done in the field-hospitals directly after the arrival of the patients, or rather, as Dr. Hennen has expressed it, with as little delay as possible. "While hundreds are waiting for the decision of the surgeon, he will never be at a loss to select individuals who can safely and advantageously bear to be operated upon as quickly as himself or assistants can offer their aid; but he will betray a miserable want of science indeed, if, in this crowd of sufferers, he indiscriminately amputates the weak, the terrified, the sinking, and the determined. While he is giving his aid to a few of the latter class, encouragement and a cordial will soon make a change in the state of the weakly or the terrified; and a longer period and more active measures will render even the sinking proper objects for operation." (*On Military Surgery*, p. 45, ed. 3.) It appears from some returns collected by Mr. Guthrie, that in the Peninsula the comparative loss, in secondary or delayed operations, and in primary or immediate amputations, was as follows:—

	Secondary.	Primary.
Upper extremities . . .	12 to . . .	1
Lower extremities . . .	3 to . . .	1

The great success attending amputation on the field of battle was also convincingly proved after the battle of Toulouse. Here, of 47 immediate amputations, 38 were cured; while of the 51 delayed operations on that occasion, 21 had fatal terminations. After the attack on New Orleans, out of 45 primary amputations 38 patients recovered, while only 2 of 7 secondary amputations terminated in the preservation of the patients. (*Commentaries*, edit. 6, p. 154 to 157.)

[This interesting historical account of the propriety of performing primary in preference to secondary amputation for gunshot wounds of the extremities, is amply confirmed by the results of the practice in the British Hospitals in the Crimean War, as will be seen by the following tables.

Relative mortality of primary and secondary amputations in the Crimean Hospitals, from 1st April, 1855, to the end of the war.

Primary.		Secondary.	
Total.	Died.	Total.	Died.
654	165	78	36

A similar return from the Hospitals on the Bosphorus, from 26th September to the 27th November, 1854, shows corresponding results:—

Primary.				Secondary.			
Total.	Died.	Remained under Treatment.	Invalided to England.	Total.	Died.	Remained under Treatment.	Invalided to England.
150	17	40	93	64	41	7	16

This long-agitated question as to the preference of primary or secondary amputation for severe gunshot wounds of the extremities, seems now unequivocally decided by the more recent experience of French and English military and naval surgeons in favour of the former, in all cases where the operation is indispensably necessary; and the earlier the operation is performed after faintness and shock have disappeared, the better will be the chance of a favourable issue.]

OF IMMEDIATE AMPUTATION.

When a limb that has received a gunshot wound cannot be saved, amputation should be immediately practised. The first four-and-twenty hours, Baron Larrey observes, is the only period that nature remains tranquil (I should say, she does not remain quiet so long), and we must hasten to take advantage of this period.

In the army, a variety of circumstances make the urgency for amputation still greater. 1. The inconvenience attending the transport of the wounded from the field of battle to the military hospitals, in carriages badly suspended, the jolting of which would produce such disorder in the wound, and in the whole body, that most patients would die in the journey, especially if it were long, and the weather either extremely hot or cold.

2. The danger of a long continuance in the hospitals; a danger which amputation materially diminishes, by changing a gunshot injury into a wound that may be speedily healed, and reducing the causes of fever, and hospital gangrene.

3. The cases in which there is a necessity for abandoning the wounded. In this circumstance, it is of importance to have amputated; for, after the operation, the patients may remain some days without being dressed, and the dressings are afterwards more easy.

OF CASES IN WHICH AMPUTATION SHOULD BE PERFORMED IMMEDIATELY.

First case.—A limb carried away by a cannon-ball, or the explosion of a shell, requires amputation without loss of time, in order to procure the patient an even, smooth incision, instead of an irregular, jagged, and highly dangerous wound. As the limb has commonly suffered a violent concussion, is almost bereft of sense and power of motion, and the bone frequently has a fissure extending some way upward, amputation is sometimes recommended to be done, if possible, above the nearest joint. Hæmorrhage, says Baron Larrey,

an accident much more to be apprehended than has been supposed, often comes on a few moments after the injury, and if prompt succour were not afforded, would put a period to the patient's existence. "I can even declare that, had it not been for the activity of the train of light surgical carriages (*ambulances volantes*) by means of which the wounded have always been dressed upon the field of battle, many soldiers would have perished from this accident alone."

If the operation is not speedily done, pain commences, fever occurs, and the functions of the system become disordered; the irritation then increases, and convulsive motions take place. If the patient should not be a victim to these first symptoms, gangrene of the stump follows, the fatal consequences of which it is extremely difficult to prevent.

At Strasburg, during the bombardment of the fort of Kell, in 1792, three volunteers, says Baron Larrey, had limbs shot off by the explosion of shells: one, an arm; another, a fore-arm; and the third, a leg. They were conveyed to the hospital for the wounded in that town, which was superintended by M. Boy. Several days were suffered to elapse before amputation was performed; not one of the patients escaped. At Mentz, after the retreat from Frankfort, several of the wounded, who had had limbs shot off, did not have amputation performed till some time afterwards, and not one of them recovered. At Nice, after the taking of Saorgio, two amputations were practised at the hospital, No. 2, one of the forearm, the other of the arm, nine or ten days after the receipt of the injuries; both the patients died. At Perpignan, Baron Larrey visited two soldiers on whom amputation had been done seven or eight days after the receipt of gunshot injuries in the action of the 14th of July, 1794. One had had a leg shot off, and the other his right arm. Notwithstanding Larrey's utmost care, he could not save their lives; one died of tetanus, the other of gangrene.

Second Case.—When a body, propelled by gunpowder, strikes a limb in such a manner as to smash the bones, violently contuse, lacerate, and deeply tear away the soft parts, amputation ought to be immediately performed. If this measure be neglected, all the injured parts will soon be seized with gangrene: and besides, as Larrey has explained, the accidents which the gravity of the first case produces, will also here be excited.

Third Case.—If a similar body were to carry away a great mass of the soft parts, and the principal vessels of a limb (of the thigh, for instance), without fracturing the bone, the patient would be in a state demanding immediate amputation; for, independently of the accidents which would originate from a considerable loss of substance, the limb must inevitably mortify. Mr. Guthrie also says, "A cannon-shot destroying the artery and vein, on the inside (of the thigh), without injuring the bone, requires amputation." (P. 185.) When, however, the femoral artery or vein is injured by a musket-ball, or small canister-shot, this gentleman recommends tying the vessel above and below the wound in it, if the nature of the case be evinced by hæmorrhage. But he believes that when both vein and artery are injured, amputation is necessary. (P. 186.) With respect to bleeding from the femoral vein, as it may easily be stopped by

moderate pressure, the propriety of using any ligature at all is questionable.

"An injury of the femoral artery (observes Mr. Guthrie), requiring an operation, accompanied with fracture of the bone of the most simple kind, is a proper case for immediate amputation; for, although many patients would recover from either accident alone, none would, I believe, surmount the two united; and the higher the accident is in the thigh, the more imperious is the necessity for amputation." (*Guthrie, On Gunshot Wounds*, p. 187.)

Fourth case.—A grape-shot strikes the thick part of a member, breaks the bone, divides and tears the muscles, and destroys the large nerves, without, however, touching the main artery. According to Larrey this is a fourth case requiring immediate amputation.

Mr. Guthrie seems to coincide on this point with Larrey: "If a cannon-shot strike the back part of the thigh, and carry away the muscular part behind, and with it the great sciatic nerve, amputation is necessary, even if the bone be untouched, &c. In this case I would not perform the operation by the circular incision, but would preserve a flap from the forepart, or sides, as I could get it, to cover the bone, which should be short." (*Guthrie, On Gunshot Wounds of the Extremities*, p. 184.)

Fifth case.—If a spent cannon-shot, or one that has been reflected, should strike a member obliquely without producing a solution of continuity in the skin, as often happens, the parts which resist its action, such as the bones, muscles, tendons, fasciæ, and vessels, may be ruptured and crushed. The extent of the internal disorder is to be examined; and if the bones should feel through the soft parts as if they were smashed, and if there should be reason to suspect from the swelling, and a sort of fluctuation, that the vessels are lacerated, amputation ought to be immediately practised. This is also the advice of Baron Percy. Sometimes, however, the vessels and bones escape injury, and the muscles are almost the only parts disordered. In this circumstance, we are enjoined to follow the counsel of De La Martinière, who recommended making an incision through the skin. By this means a quantity of thick blackish blood will be discharged, and the practitioner must await events. According to Larrey, such incision is equally necessary in the preceding case, previously to amputation, in order to ascertain the extent of mischief.

Sixth case.—When the articular heads of bones are much broken, especially those which form the joints of the foot, or knee, and the ligaments which strengthen these articulations are lacerated by the fire of a howitzer or a grape-shot, or other kind of ball, and the integuments are too much bruised and lacerated to attempt excision of the joint, immediate amputation is indispensable. (See also *Guthrie, On Gunshot Wounds*, p. 197.)

Fractures extending into the joints, and accompanied with great laceration of the ligaments and integuments, are cases of gunshot injuries indispensably requiring immediate amputation.

It is evident, says Larrey, that in this case, if we wish to prevent the patient from dying of the subsequent symptoms, amputation should be performed before twelve, or at most twenty-four,

hours have elapsed. (*Mém. de Chir. Militaire*, t. ii.)

With respect to wounds of the knee, the sentiments of Mr. Guthrie nearly coincide with those of Larrey. "I most solemnly protest (says Mr. G.) I do not remember a case do well, in which I knew the articulating end of the femur, or tibia, to be fractured by a ball that passed through the joint, although I have tried great numbers, even to the last battle of Toulouse. I know that persons wounded in that way have lived; for a recovery it cannot be called where the limb is useless, bent backward, and a constant source of irritation and distress, after several months of acute suffering, to obtain even this partial security from impending death; but if one case of recovery should take place in fifty, is it any sort of equivalent for the sacrifice of the other forty-nine? Or is the preserving of a limb of this kind an equivalent for the loss of one man?" (*On Gunshot Wounds*, p. 196.)

In the attack of the village of Merksam near Antwerp, early in 1814, a soldier of the 95th regiment was brought to our field hospital, having received a musket-ball through the knee-joint. The staff-surgeons on duty, and Mr. Curtis, surgeon of the 1st Guards, were preparing to amputate the limb, when a surgeon attached to the 95th urgently recommended deferring the operation. Superficial dressings were applied, and the patient sent to the rear. He lived several months after the accident, at times affording hopes of a perfect recovery; but in the end he fell a victim to hectic symptoms.

Indeed, such is the general unfortunate result of these cases, that Dr. Hennen lays it down as a rule in military surgery, that no lacerated joint, particularly the knee, ankle, or elbow, should ever leave the field unamputated, where the patient is not obviously sinking. (*On Military Surgery*, p. 41, ed. 3.)

According to Mr. Guthrie, fractures of the patella, without injury of the other bones, admit of delay, provided the bone is not much splintered.

Seventh case.—Larrey observes, that if a grape shot, a small cannon-shot, or a piece of a shell, in passing through the substance of a member, should have extensively denuded the bone, without breaking it, amputation is equally indicated, although the soft parts may not appear to have particularly suffered. Indeed, the violent concussion produced by the accident has disorganised many parts; the medullary substance is injured, the vessels are lacerated, the nerves immoderately stretched, and thrown into a state of stupor; the muscles are deprived of their tone; and the circulation and sensibility in the limb are obstructed. Before we decide, however, Barron Larrey cautions us to observe attentively the symptoms which characterise this kind of disorder. The case can be supposed to happen only in the leg, where the bone is very superficial, and merely covered at its anterior part with the skin.

The following are described as the symptoms: the limb is insensible, the foot cold as ice, the bone partly exposed, and, on careful examination, it will be found that the integuments, and even the periosteum, are extensively detached from it. The commotion extends to a considerable distance; the functions of the body are disordered; and all

the secretions experience a more or less palpable disturbance. The intellectual faculties are suspended, and the circulation is retarded. The pulse is small and concentrated; the countenance pale; and the eyes have a dull moist appearance. The patient feels such anxiety that he cannot long remain in one posture, and requests that his leg may be quickly taken off, as it incommodes him severely, and he experiences very acute pain in the knee. When all these characteristic symptoms are conjoined, says Larrey, we should not hesitate to amputate immediately; for otherwise the leg will be attacked with sphacelus, and the patient certainly perish.

Larrey adduces several interesting cases in support of the preceding observations.

Eighth case.—When a large ginglymoid articulation, such as the elbow, or especially the knee, has been extensively opened with a cutting instrument, and blood is extravasated in the joint, Larrey deems immediate amputation necessary. In these cases, the synovial membranes, the ligaments and aponeuroses, inflame, the part swells, erethismus rapidly takes place, and acute pains, abscesses, deep sinuses, caries, febrile symptoms, and death, are the speedy consequences. Larrey has seen numerous subjects die of such injuries, on account of the operation having been postponed through a hope of saving the limb. In his *Mém. de Chir. Militaire*, t. ii. some of these cases are detailed. Several facts of the same kind are candidly recorded by M. Velpeau. (See *Nouv. Elém. de Méd. Opér.* t. i. p. 284.) [Many of these cases, where the integuments are not too much injured, admit of excision of the ends of the bones forming the joint, whereby the limb may be preserved.]

Although a wound may penetrate a joint, yet, if it be small and unattended with extravasation of blood, M. Larrey informs us, it will generally heal, provided too much compression be not employed.

When two limbs have been at the same time so injured as to require amputation, we should not be afraid of amputating them both immediately, without any interval. We have, says Larrey, several times performed this double amputation with almost as much success as the amputation of a single member. He has recorded an excellent case in confirmation of this statement. (*Mém. de Chir. Militaire*, t. ii. p. 478.)

When a limb is differently injured at the same time in two places, and one of the wounds requires amputation (suppose a wound of the leg with a splintered fracture of the bone, and a second of the thigh, done with a ball, but without any fracture of the os femoris or other bad accident), Larrey recommends us first to dress the simple wound of the thigh, and amputate the leg immediately afterwards, if the knee be free from injury. When it is necessary to amputate above this joint, the less important wound need not be dressed till after the operation, provided it can be comprehended in the section of the member, or be so near the place of the incision as to alter the indication. When the wound demanding amputation is the upper one, the operation of course is to be done above it, without paying any regard to the injury situated lower down.

Ninth case.—To the foregoing species of gunshot wounds, pointed out by Baron Larrey as urgently requiring immediate amputation, my own

experience, and the observations of Dr. Thomson, justify me in adding compound fractures of the thigh from gunshot violence. I am particularly glad that the latter gentleman has devoted a proper degree of attention to these cases; for the opportunities which I had of judging when abroad, incline me to believe that military surgeons are hardly yet sufficiently impressed with the propriety of immediate amputation in gunshot fractures of the thigh. There were brought into my hospital at Oudenbosch, in 1814, about eight of such cases, all in the worst state for an operation, because several days had elapsed after the receipt of the injuries. All these patients died, excepting one, whose fracture was not far above the condyles, and I do not know that he ever regained a very useful limb. Another had indeed been rescued by amputation from the dangers of the injury, but was, unfortunately, lost by secondary hæmorrhage about three days after the operation. The bleeding was almost instantly suppressed; yet such was the weakness of the patient, that the irritation of securing the vessel, and the loss of blood together, destroyed at once every hope of recovery. Were I to judge, then, from my own personal observations in the army, and from some other cases which I saw under my colleagues, I should, without hesitation, recommend immediate amputation in all cases of compound fractures of the thigh caused by grape-shot, musket-balls, &c. If there are any exceptions to this advice, they are such as are specified in the article AMPUTATION.

"Gunshot fractures of the thigh (says Dr. J. Thomson) have been universally allowed to be attended with a high degree of danger; indeed, till of late years, very few instances have been recorded of recovery from these injuries. Ravaton acknowledges that in his long and extensive experience he had never seen an example of recovery from a gunshot fracture of the thigh; and Bilguer, in his calculations with regard to those who recover from gunshot fractures, sets aside those of the thigh-bone as being of a nature altogether hopeless. In the present improved state of military surgery, instances sometimes occur of recovery from this fracture; but of these the number will be found, I believe, to be exceedingly small in comparison with those who die, particularly when the fracture has had its seat above the middle of the bone."

According to the observation of Percy, scarcely two of ten recover who have suffered gunshot fractures of the thigh-bone. Mr. Guthrie, who seems to have paid great attention to this subject, says that "upon a review of the many cases which I have seen, I do not believe that more than one-sixth recovered so as to have useful limbs; two-thirds of the whole died either with or without amputation; and the limbs of the remaining sixth were not only nearly useless, but a cause of much uneasiness to them for the remainder of their lives." (See *Guthrie, On Gunshot Wounds*, p. 191.)

"In fractures by musket-bullets of the lower part of the thigh-bone (says Dr. Thomson) recovery not unfrequently takes place; and both Schmucker and Mr. Guthrie conceive that they are injuries in which amputation may be delayed with safety. It would be very agreeable that this opinion should be confirmed by future experience; but it appears to me that before it can be received as a maxim in military surgery, much more exten-

sive and accurate observation than we yet possess will be required, with regard to the proportion of those who recover without amputation, or after secondary operations, and of those who recover after primary amputation. Of those who had suffered this injury, we saw comparatively but a small number recovering in Belgium, and they had been attended with severe local and constitutional symptoms." (See *Obs. made, &c. in Belgium*, p. 247, *et seq.*)

In the article AMPUTATION, I have described the manner in which balls produce fissures of several inches in length in the thigh-bone. This state of the bone, observes Dr. Thomson, must be very unfavourable to recovery, and his conclusion is, that in general, even in fractures of the lower part of the thigh-bone, a greater number of lives will be preserved in military practice by immediate amputation, than by attempting the cure without that operation. "When the bone appears, on a careful examination, to be broken without being much splintered, and when the patient can be removed easily to a place of rest and safety, it may be right to attempt to preserve the limb; but if the bone be much splintered, or if the conveyance is to be long or uncertain, it will, in most instances, I am convinced, be a much safer practice, even in fractures of this part of the thigh-bone, to amputate without delay.

"Musket-bullets, in passing through the femur, near to the knee-joint, produce fissures of the condyles, which generally communicate with the joint. These cases, like those in which the bullets have passed directly through the joint, require either excision of the joint or amputation.

"The writings of military surgeons contain but few histories of cases in which the thigh-bone had been fractured above its middle by the passage of musket-bullets. These are cases, I believe, which have generally had a fatal termination; and the danger attendant upon the amputation which they require, seems long to have deterred surgeons from attempting to ascertain what advantages might be derived from the employment of that operation. Schmucker recommends, and states that he had practised with success, immediate amputation in those cases in which a sufficient space was left below the groin for the application of the tourniquet. It is curious to remark, in the history of amputation, how long surgeons were in discovering the ease and safety with which the femoral artery might be compressed by the fingers, or pads, in its passage over the brim of the pelvis. M. Boy, from the immediate danger, protracted suffering, and ultimate want of success, which he had observed to follow this kind of injury, urges strenuously the propriety of immediate amputation. Mr. Guthrie's opinion, with regard to the dangerous nature of these injuries, and the advantages to be derived in them from immediate amputation, coincides in every respect with those of Schmucker and Boy. He observes, that those whose thigh-bone has been fractured in its upper part by a musket-bullet, generally die, with great suffering, before the end of the sixth or eighth week, and that few even of those escape in whom the bone has been fractured in its middle part. Of the few whom we saw, who had survived gunshot fractures in the upper part of the thigh-bone, in Belgium, scarcely any one could be said to be in a favourable condition. In all the limbs were much contracted,

distorted, and swollen, and abscesses had formed round and in the neighbourhood of the fractured extremities of the bones. In some instances, these abscesses had extended down the thigh; but more frequently they passed upwards, and occupied the region of the hip-joint and buttocks. In several instances, in which incisions had been made for the evacuation of matter, the fractured and exfoliating extremities of the bones, sometimes comminuted, and sometimes forming the whole cylinder, could be felt bare, rough, and extensively separated from the soft parts which surrounded them. In other instances, these extremities were partially enclosed in depositions of new bone, which, from the quantity thrown out, seemed to be present in a morbid degree. It was obvious that, in all of these cases, several months would be required for the reunion of the fractured extremities; that, in some, much pain and misery was still to be endured from the processes of suppuration, ulceration, exfoliation, and ejection of dead bone; that, in some cases, the patients were incurring great danger, from hectic fever, and from diarrhoea; that the ultimate recovery in most of them was doubtful, and that, of those in whom this might take place, there was but little probability that any would be able to use their limbs! The sight of these cases (says Dr. Thomson) made a deep impression upon my mind, and has tended to increase my conviction that this is, of all others, the class of injuries in which immediate amputation is most indispensably required." (See *Obs. &c. in Belgium*, p. 254—258.)

Dr. Thomson adds, that what has been said of the danger of fractures, produced by musket-bullets, in the upper part of the femur, is true in a still greater degree of those which have their seat in the neck or head of that bone. In such instances, Dr. Thomson joins the generality of modern army surgeons in strongly recommending amputation at the hip-joint, a subject of which I have already spoken. (See AMPUTATION.)

[The more recent experience of the Crimea has confirmed the dangerous nature of these severe injuries of the thigh-bone, and the amputations which many of the cases underwent were followed by scarcely better results. In amputations of the upper third of the thigh there were few recoveries. The French and Russians eventually almost abandoned operations on this portion of the limb. Amputations at the middle and lower third were much more successful. The following table,

	PRIMARY.			SECONDARY.		
	Operations.	Deaths.	Ratio per Cent.	Operations.	Deaths.	Ratio per Cent.
Upper third	38	33	86·8	1	1	100
Middle third	56	31	55·3	9	7	77·7
Lower third	46	23	50·0	14	10	71·4

extracted from the *History of the Crimean War*, from the 5th of April 1855 to the close of the war, the only period in which the returns distinguish the results at the upper middle and lower third, shows the relative mortality of each.]

ON GUNSHOT WOUNDS IN WHICH AMPUTATION MAY BE DEFERRED.

If, says Baron Larrey, it be possible to specify the cases in which amputation ought to be immediately performed, it is impossible to determine *a priori* those which will require the operation subsequently. One gunshot wound, for example, will be cured by ordinary treatment, while another, that is at first less severe, will afterwards render amputation indispensable, whether this be owing to the patient's bad constitution or the febrile disturbance induced. However this may be, the safe rule for fulfilling the indication that presents itself, is to amputate consecutively only in circumstances in which every endeavour to save the limb is manifestly in vain. Upon this point Larrey's doctrine differs from that of Faure.

The latter practitioner admits cases, which he terms cases of the *second kind*, in which he delays amputation, not with any hope of saving the limb, but in order to let the first symptoms subside. The operation, done between the fifteenth and twentieth day, appears to him less dangerous than when performed immediately after the receipt of the injury. At the above period, according to M. Faure, the commotion occasioned by the gunshot injury is dispelled; the patient can reconcile himself to amputation, the mere mention of which fills the pusillanimous with terror in a greater or lesser degree; the debility of the individual is no objection; and it is laid down as an axiom "that the consequences of every amputation, done in the first instance, are in general extremely dangerous." In support of this theory M. Faure adduces ten cases of gunshot injuries, in which, after the battle of Fontenoy, the operation was delayed, in order that it might afterwards be performed with more success: a plan which, according to the author, proved completely successful. (See *Prix de l'Acad. de Chir.* t. viii. éd. in-12.)

This division of cases for amputation into two classes, not consistent with nature, Larrey conceives has been the cause of a great deal of harm. Very often the partisans of M. Faure have not dared to resort in the first instance to amputation, the dangers of which they exaggerate; while on other occasions they have amputated consecutively without any success.

Larrey argues that the effects of commotion, instead of increasing, gradually diminish and disappear after the operation. He will not even admit that the patient's alarm ought to be a reason for postponing the operation, because the patient, just after the accident, will be much less afraid of the risk which he has to encounter than at the expiration of the first four-and-twenty hours, when he has had time to reflect upon the consequences of the injury, or of amputation, a remark made by the illustrious Paré.

"Experience agreeing with my theory (says Baron Larrey) has proved both to the army and navy surgeons, that the bad symptoms which soon follow such gunshot injuries as must occasion the loss of a limb, are much more to be dreaded than those of immediate amputation. Out of a vast number of the wounded, who suffered amputation in the course of the first four-and-twenty hours after the memorable naval battle of the 1st of June 1794, a very few lost their lives. This fact has been attested by several of our colleagues, and especially by M. Fercoc, surgeon of the ship *Le Jemmapes*."

The following is said to be an extract from one of his letters:—

“After the naval engagement of the 1st of June 1794, a great number of amputations were done immediately after the receipt of the injuries. Sixty of the patients whose limbs had been thus cut off were taken to the naval hospital at Brest, and put under the care of M. Duret. With the exception of two who died of tetanus, all the rest were cured; and there was one who had had both his arms amputated. The surgeon of the *Téméraire*, which ship was captured by the English, was desirous, in compliance with the advice of their medical men, to defer the operation which many of the wounded stood in need of, till his arrival in port; but he had the mortification to see them all die during the passage,” &c.

Larrey next acquaints us that when he was sent to the army of Italy, in 1796, he had also the pain of seeing in the hospitals great numbers of the wounded fall victims to the confidence which many of the surgeons of that army placed in the principles of M. Faure. Buonaparte saw that the *ambulance volante* was the only thing that, in the event of fresh hostilities, could prevent such accidents, and in consequence of his orders Larrey formed the three *division d'ambulance*, which are described in his *Mémoires de Chirurgie Militaire*.

Since this period it has always been customary in the French armies on the day of battle to make every preparation for performing amputations as speedily as possible. The mere sight of these *ambulances* (always attached to the advanced guard), says M. Larrey, encourages the soldiers, and inspires them with the greatest courage. On this occasion the following anecdote is cited from Ambrose Paré:—This famous surgeon having been urgently sent for by the Duke de Guise, besieged in Mentz, to attend the wounded of his army who were in want of assistance, Ambrose Paré was shown to the frightened soldiers at the breach. Upon this they immediately filled the air with shouts of the most lively joy, and cried out, “*Nous ne pouvons plus mourir, s'il arrive que nous soyons blessés, puisque Paré est parmi nous.*” Their courage revived, and their confidence in this skilful surgeon contributed to the preservation of a place before which a formidable army was destroyed.

Larrey desires us to interrogate the invalids who have lost one or two of their limbs, and nearly all will tell us that they suffered amputation a few minutes after the accident, or in the first four and twenty hours. “If Faure now retains any partisans,” says Larrey, “I recommend them to repair to the field of battle the day after an action: they would then soon be convinced that, without the prompt performance of amputation, great numbers of soldiers must inevitably lose their lives. In Egypt this truth was particularly manifested.”

The following communication upon this point was made to Baron Larrey by M. Masclet, a French surgeon on duty at Alexandria:—

“In the naval hospital of this port, I have seen eleven soldiers, or sailors, who were wounded in the naval action off Aboukir, and who had suffered amputation in the first four and twenty hours. In five of these cases the operation had been done on the arm; in two, on the thigh; and in three others, on the leg. All these men are recovering.

In the army hospital there have been only three thigh amputations, which we performed seven or eight days after the battle, and these three patients died a few days after the operation, although the operation was done methodically, and no grave symptoms prevailed at the time of its performance. You see, sir, experience has, in this instance, quite confirmed your principles.”

In 1780, during the American war, as we are informed by Larrey, the surgeons of the French followed the maxim then generally adopted in France, that the operation should not be undertaken till after the subsidence of the first symptoms. Almost all the patients thus treated died after the operation. On the contrary, the Americans, who had the boldness to amputate immediately (or in the first four-and-twenty hours) upon many of their wounded countrymen, lost only a very few. Yet M. Dubor, at that time surgeon to the Artois dragoons, and from whom Larrey has collected this fact, states that the situation of the hospital for the French wounded was, on many accounts, the most advantageous. (*Dubor, Thèse Inaugurale, soutenue 16 Sept. 1803, à l'Ecole de Strasbourg.*)

Admitting that, by a concurrence of fortunate circumstances, which are not always to be calculated upon, some patients escape the danger of the first symptoms, as Larrey remarks, this proves nothing in favour of doing the operation afterwards; it must be seen what nature will do towards the event of the case. If, at the end of twenty or thirty days, the prognosis is as bad as it was previously, amputation cannot be avoided. Thus all the sufferings which the patient has endured have been undergone for nothing, and the operation will now be attended with considerable risk, inasmuch as the patient is in a dangerously weakened state. If nature revives at all, no doubt the success of the operation becomes more probable; but, in this case, the surgeon, instead of having recourse to amputation, should redouble his efforts to preserve the limb.

CASES DEMANDING AMPUTATION CONSECUTIVELY.

First case. A spreading Mortification.—If the disorder were owing to an internal and general cause, it would be rashness to amputate before nature had put limits to the disease. Larrey describes this species of gangrene as being distinguished from that kind which is named *traumatic* by the symptoms which precede and accompany it. These symptoms are similar to those which are observed in nervous and typhoid fevers. Here the operation ought to be deferred, and endeavours made to combat the general causes with regimen and internal medicines.

But when gangrene is *traumatic*, Larrey advises the limb to be immediately cut off above the disorganised part. Several facts in support of this doctrine are related by this experienced surgeon in his *Mém. sur la Gangrène Traumatique*. (See MORTIFICATION.)

In that part of the Dictionary will be found additional observations in favour of the practice adopted and recommended by Larrey, which is so opposite to that inculcated by Sharp, Pott, and the generality of writers.

In the article AMPUTATION, I have noticed a particular case of gangrene, which has been pointed

out by Mr. Guthrie as demanding the early performance of amputation, and a deviation from the old rule of waiting till the mortification has ceased to spread. (*On Gunshot Wounds of the Extremities*, p. 63, &c.)

Second case. Bad State of the Wound.—It often happens that, in gunshot wounds complicated with fractures, notwithstanding the most skilful treatment, the discharge becomes of a bad quality; the fragments of bone lie surrounded with the matter, and have not the least tendency to unite; the patient is attacked with hectic fever, and a colliquative diarrhoea. Under these circumstances, life may sometimes be preserved by amputation.

[Secondary amputation may become necessary on gangrene setting in after ligature of a main vessel of a limb, or a vessel may be secondarily injured by a fractured bone where it may be impossible to secure both ends of the bleeding vessel, and the hæmorrhage cannot be arrested in any other way: in such a case, amputation must be had recourse to as a last resort.]

Third case. Bad State of the Stump.—In hospitals, the cure of amputation is sometimes prevented by a fever of a bad character. The stump swells, the integuments become at first retracted, and then everted and diseased a good way upwards. The wound changes into a fungous ulcer, the cicatrization of which is hindered by the deep disorder of the bone and the ulceration of the soft parts.

The extremity of the bone projects. In order to remedy this last evil, it has been proposed to saw off the projecting part of the bone, and, with this, even to amputate all the flesh beyond the level of the skin. Larrey condemns such practice as unnecessary and dangerous, and he recommends giving nature time to bring about exfoliation. (See *Mém. de Chir. Militaire*, t. ii.) Exceptions to this advice, however, are met with.

[Larrey was of opinion that secondary amputation, performed on the very first appearance of acute tetanus, or for the chronic form of that disorder, checked the disease. One of his patients recovered after undergoing the operation, and a few other cases are recorded where beneficial results followed. This doctrine is, however, entirely renounced both by the modern French and English surgeons; and no one, that I am aware of, now recommends amputation for the acute form of that malady.]

In certain, though rare instances, secondary amputation may be demanded, where hæmorrhage persists from a wound or compound fracture in which all other means have failed to restrain it. Styptics, pressure either on the wound, or compression of the main artery, or ligature, ought to be resorted to previous to having recourse to amputation; and this measure should only be adopted as a last resource for the preservation of the life of the patient. Such a case, I believe, only once occurred in the campaign before Sebastopol.]

ture as much as possible, in order that the weight of the organ might assist in keeping it in its proper position.

Musket balls, and this observation refers more particularly to the spherical form, sometimes take

a devious course in the region of the face, such as entering at the external meatus of the ear and passing out at the nose, or passing in at the frontal sinus and escaping by the mouth. (*Hennen's Military Surgery.*)

Treatment.—For restraining the hæmorrhage, which is often a matter of much moment and considerable difficulty, styptic applications or plugs of lint pressed into the wound are necessary. Perchloride of iron, tincture of matico, and acetate of lead, have all been found useful, or lumps of ice placed in the wound. As a last resource, when these means and pressure have failed, the external carotid artery may be required to be ligatured for wounds of one or more of its branches, for it is seldom in deep wounds that you can get at the bleeding vessel or vessels themselves.

To diminish the swelling and inflammation following upon wounds of the tongue, it will be necessary to apply leeches, or scarify, or make incisions, and to freely administer antimonials and mercury. For adjustment of the soft parts in these wounds of the face, especially after shell injuries, the use of sutures is found very beneficial.

“In fractures of the bones of the face from gunshot, we make an exception to the general rule of removing fragments which are nearly detached. The large supply of blood which is sent to every structure in this region, enables pieces of bone to resume their full connection with the other tissues, when detached, in a way that would be fatal to similarly placed portions in other parts. Hence the rule, not to extract any spicula whose attachment has not been completely destroyed, and whose direction is not opposed to a proper union of

the broken parts. The exfoliation which follows in injuries of the bones of the face, is slight as compared with those of other parts." (*Macleod, Surgery of the Crimean War*, p. 222.)

In wounds of the eyelid and its appendages, great care is necessary for the nice adjustment of the divided portions; the use of fine sutures for this purpose is absolutely necessary.]

GUNSHOT WOUNDS OF THE NECK.

[Superficial wounds of this region do not differ from the corresponding injuries inflicted on other parts of the body, and require no particular description or peculiar treatment. When the deeper and more important structures are implicated in the injury, we usually have them followed by restlessness, cough, oppressed breathing, nausea, great irritability of the stomach, and sundry nervous affections, the consequence of injury to the communicating nervous distributions so abundant in this situation. (*Hennen's Military Surgery*, edition 3, p. 361.)

In no wounds are there more remarkable escapes for the main blood-vessels than in injuries occurring in this region. Musket-balls frequently traverse close to the vessels, even between the artery and vein without wounding either. A case of this kind came under my notice in the campaign before Sebastopol, where a full sized Minié bullet passed between the subclavian artery and vein, separating

them slightly, but without wounding in any degree the coats of either.

Wounds of the larynx are not uncommon, as might be expected from its size, prominence, and superficial position; more or less complete aphonia is a necessary consequence of such injury. This failure of the voice lasts for a considerable period, but is eventually restored when the wound heals. A troublesome and continued cough very generally accompanies these wounds, often leading to marasmus, and symptoms closely allied to phthisis. In some instances an aggravated form of inflammation ensues, which spreads to the lungs and threatens the life of the sufferer. Dyspnoea is often very urgent, and renders the operation of tracheotomy absolutely necessary for its relief. Emphysema is not an uncommon attendant of wounds of this organ and the trachea. The cartilages sometimes become thickened and eroded, and portions exfoliate. All injuries involving the larynx and trachea must be looked upon as dangerous; they are attended with much suffering and distress to the patient, require much attention and careful treatment, and the cure is often tedious and prolonged.]

The practice of Baron Larrey furnishes a curious example, in which the epiglottis of a French soldier was shot off at the battle of Alexandria, on the 21st of March 1801. The ball entered at the angle of the jaw, crossed the throat obliquely, and came out at the opposite side of the neck. The base of the tongue was grazed, and the epiglottis shot away; the patient spat it up after the accident, and showed it to the surgeon who first saw him.

The patient was not in much pain; but his voice was hoarse, feeble, and scarcely audible.

When he first attempted to swallow, he was seized with a convulsive suffocating cough, attended with vomiting. Annoyed by thirst, which the extreme heat of the weather and the irritation of the wound excited, he incessantly repeated his attempts to drink; but always with the same result. Four days were passed in this deplorable condition. He already experienced violent complaints in his stomach; continued loss of sleep; he had a small accelerated pulse; and was beginning to look thin.

If the patient had been abandoned to the resources of nature, he would have died in the course of a few days. The most urgent indication was to appease the hunger and thirst. An elastic gum tube was introduced into the pharynx, and by means of it the patient was given some drink, which relieved him much, and afterwards some rich broth. The patient was fed in this manner for six weeks, at the end of which time he was able, without the assistance of the tube, to swallow thick panado, and thickened rice, made into little balls. The power of speech and deglutition in time became more perfect, in consequence, as Larrey imagines, of an enlargement of the arytenoid cartilages, and an expansion of that part of the base of the tongue which lies next to the glottis having formed a sort of substitute for the epiglottis. (*Mém. de Chir. Militaire*, t. ii. p. 145—149.)

The foregoing case illustrates the utility of elastic gum tubes for conveying nourishment and medicines down the œsophagus in some wounds of the throat. All practitioners should be duly

impressed with the necessity of having such instruments always at hand. The patient, whose case is above recited, owed his preservation altogether to this means, without which he must have been starved to death.

In the 4th vol. of the above work, p. 247, is recorded another case, in which a gunshot wound, that took away the epiglottis, and broke the os hyoides, was successfully treated.

[Wounds of the pharynx not unfrequently occur in common with the larynx; the same musket-ball passing through both structures. Many of these injuries are produced by a bullet entering some part of the face and escaping at the neck. Difficult deglutition is the most prominent symptom of this lesion.

The œsophagus is much more rarely wounded. Baron Larrey records only one example of this injury which fell under his notice during an extensive experience of more than thirty years. The symptoms manifested in this lesion are an ardent and inextinguishable thirst, arising from injury to the pneumogastric plexus of nerves, and the food or drink swallowed passing out of the wound. The patient therefore requires to be supported by liquid nourishment introduced through a flexible tube, and care should be employed in doing this that the instrument does not pass through the wound, or re-open it if it is partially closed. Larrey recommends that the thirst should be allayed by lavements and slightly tepid baths, and the lips be constantly moistened. He narrates the case which fell under his care, a very interesting and instructive one, though it terminated fatally; the wound having been unfortunately re-opened after closure, from the patient freely partaking of solid food and drink before the union was sufficiently established.

Division or wounds of the carotid arteries mostly terminate fatally from hæmorrhage on the field. Should surgical assistance be speedily at hand, the vessel must be temporarily compressed above and below the wound, and afterwards both ends of the divided artery secured by ligature. As a consequence of the division or injury of some one or more of the cervical nerves, partial or complete paralysis of the upper extremity may ensue; this occurrence follows immediately upon the infliction of the wound in some instances, but not till after the lapse of some days in others; in general such injuries are accompanied with severe pain. The lodgment of balls deeply in the neck, near the large nerves, occasions, according to Baron Larrey, severe tetanic affections; sometimes, balls so lodged are observed occasionally to become encysted, but they are more generally followed by suppuration, and their removal becomes a matter of necessity, if there is a possibility of its being accomplished; as a rule, whenever they can be reached, extraction should be attempted, as they are oftener than not followed by troublesome consequences. Wounds of the posterior region of the neck are unattended with danger unless they penetrate to the spinal canal, fracturing the vertebræ, or, what is still more serious, injuring the spinal marrow and leading to a fatal result.

The treatment of these wounds generally should be antiphlogistic, especially where the larynx or trachea is concerned, and opiates should be prescribed to allay the frequent and harassing cough. For further information on this subject, and for the treatment, consult the article WOUNDS.]

in the preceding pages." (*Hennen, loc. cit.*) In these cases, the absence of bloody expectoration directly after the injury, the undisturbed state of respiration, and the greater freedom from oppression, anxiety, syncope, and other bad symptoms, than in cases where the lungs are injured, form grounds for a correct opinion on the true nature of the accident.

[Hæmorrhage from the lungs by the mouth, or bloody expectoration as it is termed, is by no means a certain sign of wound of those organs. Several cases of decided wound of the lung (as shown afterwards by post-mortem examination) that occurred before Sebastopol were marked by the absence of such bloody sputa, and Dr. Frazer in a recent monograph states it as his opinion that "spitting of blood" is a very deceptive diagnostic sign of lung wound; out of nine fatal cases that he has collected together, only one had hæmoptysis; and in seven cases in which the lung was unwounded, two only had hæmoptysis. In some experiments which he performed upon dogs, to see what would be the effects that would ensue, in none of them did he find hæmoptysis appear.]

M. Appia also states that bloody expectoration is not a pathognomonic character of penetration of the lung. He has often seen it accompanying simple contusions or superficial wounds.]

It cannot be supposed that adhesions always take place round the opening of a gunshot wound in the chest, because the lung sometimes collapses, and becomes considerably distant from the pleura, especially when the communication established between the atmospheric air and the cavity of the thorax is free and direct. However, as adhesions are extremely common between the outer surface of the lung and the inner surface of the pleura costalis, they must, in many instances, exist before the receipt of a wound, and, of course, prevent the usual collapse of the lung.

[It is necessary, with reference to exactitude in our comparison of gunshot wounds of the chest, to arrange them into classes.]

First. With regard to those in which the soft external parietes only are concerned, such as skin and muscles, simple injuries like these do not afford any peculiarity distinguishing them from similar wounds of other regions, but occasionally you have inflammation of the contused organs set up, where no primary injury of them could be discovered. Two deaths from this cause appear in the Sebastopol returns, where fatal pleuropneumonia supervened on bullet wounds of the walls of the chest, though in neither instance, as the post-mortem examination revealed, had the pleura been opened.

Secondly. Wounds complicated with injury to the bony or cartilaginous portion of the parietes. Although these are serious cases, yet, when the cavity of the chest has escaped injury, they do not appear to be of a very fatal character: only one death is recorded in this class from among twenty-four cases occurring before Sebastopol; it was followed by acute inflammation of the pleura of the injured side, which extended to the lung and pericardium.

Thirdly. Those that produce lesion of the contents without opening the cavity. This form of injury, although not often occurring, does sometimes follow as a direct consequence of the external violence, without the bony or cartilaginous walls being broken, and without penetration of the cavity.

It cannot at first always be distinguished from those of the second class; hence our prognosis should be guarded. The symptoms denoting this complication do not always take place immediately, but after a time severe hæmoptysis may come on, or pleuropneumonia may supervene.

Fourthly. Penetration of the cavity, which may or may not be aggravated by lodgment of the missile, the lung being unwounded. This kind of wound may be effected by a lance, bayonet, bullet, or fragment of shell. The danger of these injuries is very often primary, where a large vessel of the parietes, such as an intercostal artery, is divided, which however, practically, seems to be a rare occurrence, or death may be the consequence of violent pleuropneumonia coming on. In clean cut lance or bayonet wounds, in which there is but little bleeding, the lips of the wound must be nicely adjusted and brought together, and in fortunate cases only a sufficient amount of lymph may be thrown out necessary to agglutinate the edges of the wound of the pleura and surface of the lung. The same happy result may and does follow upon bullet wounds. Lodgment of the missile in the cavity of the pleura is in the very large majority of instances fatal; indeed it has been stated to be a much more dangerous wound than where the cavity has been completely perforated, and the ball has made its escape. Such a conclusion appears to be justified by the result of 41 cases returned in the latter half of the Crimean war: 38 died and 3 were invalided, and some doubts were entertained as to whether the ball had really lodged in these three cases of recovery.

Fifthly. Penetration of the pleura with perforation or lodgment of the missile in the lung. A large number of these cases never come under treatment at all. They die, many of them almost instantly, on the field of battle, from hæmorrhage poured out from a large vessel or vessels in, or near the root of, the lung, or from suffocation, when the large bronchial tubes are opened and become choked with blood. Others again only survive a short period after admission into hospital, dying from repeated and copious bleeding, either from the mouth or the wound, or from both. This hæmorrhage may arise from a wound of an artery of the chest walls, either produced by the missile or by the fractured bone, or from the wounded lung itself, and this may be done by the ball or subsequently by the fractured rib. One-twelfth of the deaths after an action in the field are calculated to arise from wounds of the chest, according to M. Scrive, and one-twentieth after a siege. In those cases that survive for a longer period, the danger will be primary, from hæmorrhage; secondarily, from inflammation; and lastly, from extensive suppuration. Neither emphysema nor secondary hæmorrhage appears to have led to a fatal termination in any instance before Sebastopol. It rarely happens that a ball enters the cavity of the chest without fracturing one or more ribs, and frequently a fragment or fragments of the broken bone, or some portion of the clothing or accoutrements, is carried in along with the ball.]

As the general symptoms and treatment of wounds of the chest are detailed in the article WOUNDS, I shall not here detain the reader long upon the subject. When a patient has been shot in the chest, the most important indication in the first instance is to check the hæmorrhage, should it

exist. It is this which, in many instances, threatens the life of the sufferer, and which must be the first attended to; the second point is to prevent and subdue inflammation of the lungs and pleura. In few other cases can repeated and large bleedings be so advantageously practised. Here there will not be so much danger of an extravasation of blood as in stabs; and, even if an effusion of that fluid were to happen within the cavity of the pleura, the opening would generally be sufficient for its escape.

In this last kind of case, when attended in the beginning with bleeding, Baron Larrey particularly insists upon the advantage of immediately bringing the edges of the wound together with adhesive plaster, instead of leaving it open as advised by the generality of writers; and he endeavours to prove, that this immediate closure of the wound has great effect in stopping the hæmorrhage from the pulmonary vessels. Supposing an extravasation of blood in the chest were to follow, he argues, that it would be better to let it out afterwards by a suitable incision, than to suffer the patient to perish of hæmorrhage at once by not closing the wound. (*Mém. de Chir. Mil.* t. iv. p. 151, &c.) Dr. Hennen is in favour of the same practice. (*On Military Surgery*, p. 373, ed. 3.) [Mr. Guthrie is of the same opinion. In large penetrating wounds of the chest, with injury of the lung, he says, "It has been observed that the patient breathes most easily when the external wound has been covered, and has been hardly able to breathe when it was opened, which is attributed to the air getting into that side of the thorax in inspiration, instead of entering the lung by the trachea. If the wound admit of being well closed, the difficulty of breathing diminishes; adhesion may take place, and the inflammatory action within the chest may terminate." Writers generally are of the same opinion, and it would appear to be the established and correct line of procedure to adopt in all cases, in the first instance. (*Vide Commentaries*, edit. 6, f. 453.)] In a penetrating gunshot wound of the chest the surgeon should extract all extraneous substances, and splinters of bone within reach, and even dilate the external wound for this purpose, if necessary. Light unirritating dressings are then to be applied. The patient may now be (comparatively speaking) easy, until the spitting of blood, and danger of suffocation, from inward hæmorrhage, come on, when the lancet must be employed; "and if, by this treatment, repeated as often as circumstances demand, the patient survives the first twelve hours, hopes may begin to be entertained of his recovering from the immediate effects of hæmorrhage," and until this danger is over, as Dr. Hennen truly observes, the lancet is the only thing which can save life. Afterwards, when the paroxysms of pain, the sense of suffocation, and the return of hæmorrhage, have become more moderate, digitalis may be prescribed with the most beneficial effect; and if the cough be very troublesome, no medicine is more useful than the spermaceti mixture with opium.

[Opinions seem to have undergone great change with reference to the large amount of bleeding necessary in gunshot wounds of the chest. The old Peninsular surgeons seemed to have reduced their patients to the last stage of weakness by repeated bleedings. Amongst the moderns we find Dr. Frazer (see *Penetrating Wounds of the Chest*, p. 126, 127) adducing strong arguments to show that bleed-

ing is not only not necessary, but very often injurious; and I cannot forbear quoting the following remarks from *The Surgical History of the Crimean War*, by Dr. Mathew, on this subject. The whole article is replete with masterly observations. He says, "Supposing the first danger of death by excessive loss of blood not to have arisen, in consequence of no large vessel having been wounded, or this danger to have passed over, the means adopted by nature to repair the mischief appear to be the exudation of plastic material glueing the various parts involved in the injury together, and thus isolating them; and the more effectually and perfectly she does this, the greater is the chance of safety to the patient; and, as before stated, in discussing the subject of wounds of the head, we believe venesection (for any other purpose than that of a styptic, as pointed out above) to be not only useless, but positively and actively injurious, as tending to prevent or render less perfect the adhesive process. The doctrine of the older surgeons, that adhesion depended upon a less degree or smaller amount of the same process which produces pus, and that as inflammation was almost certain to follow these injuries, prophylactic bleedings, to as great an extent as could be borne with safety to life, should be employed, as tending to limit the inflammation to the less degree, or the adhesive stage, seems not at all tenable in the present day. Adhesion and pus formation seem to depend upon two essentially different processes, although the term inflammation has been applied to both; and although we are at present not fully acquainted with the nature of the difference, the opinion appears to be daily gaining ground, that the too early abstraction of large quantities of blood favours the latter, while there can be little question that it impedes the former process. We are, however, by no means prepared to state that exceptional cases of plethora, in which such prophylactic venesection may be beneficial, do not occasionally occur; but they appear to be rare, and indeed are not likely to exist among soldiers on active field-service. Practical experience also, to which all theoretical opinions must give way, seems, during the late war, to point in this direction, and to do so independent of, and making allowance for, the cachectic state before alluded to, into which the bulk of the army had at one time fallen."

Mr. G. Lawson (see *Gunshot Wounds of the Thorax*) gives it as his opinion, that bleeding in these injuries is not called for as recommended by Mr. Guthrie, Hennen, and the older army surgeons, and certainly was not all applicable to the cases occurring in the late war in the Crimea.

After the immediate danger of hæmorrhage either from the wound or the lungs has passed, our attention may be required for the removal of fragments of bone projecting into the cavity, which may irritate or wound the lung; for, as has been before remarked, these wounds seldom occur without fracture of one or more ribs, and any foreign substance within reach must be carefully looked for and withdrawn. Enlargement of the wound may be requisite for this purpose.]

When a ball lodges, without falling into the chest, it may lie either in the substance of the parietes of this cavity between the muscles, or in one of the intercostal spaces, and continue there a very long time without causing much inconvenience, or making its way outward. But,

GUNSHOT WOUNDS OF THE ABDOMEN.

[These injuries are judiciously classified under three heads; first, those that concern the abdominal walls only, without penetration of the cavity; secondly, wounds of the parietes opening into the cavity, but without implicating any of the viscera; and thirdly, penetration of the cavity, complicated with lesion of one or more of the hollow or solid viscera. It is not essential to every case of wounded or injured viscera that it should necessarily be accompanied by perforation or other lesion of the abdominal walls; many instances are recorded of laceration of the liver, or spleen, or rupture of the intestine, where the parietes of the cavity were but little, if at all, injured. Four fatal cases occurred from rupture of viscera without external wound, before Sebastopol; in two of these there was rupture of the liver, one of the spleen, and one of the intestines.]

The muscular portion of the walls of the abdomen, according to Mr. Guthrie, are subject to absorption after a severe bruise from gunshot injury, rendering the portion liable to rupture; the division of its walls by a sharp cutting instrument is attended by the same consequence, and it never fails to occur after a bullet wound which has penetrated the cavity. (*Commentaries of Surgery*, edit. 6, p. 535-6.) No case of ruptured muscle, followed by atrophy and protrusion of the abdominal contents, is recorded in the returns from Sebastopol.

Musket-balls, impinging obliquely against the wall of the abdomen, are described as sometimes making a circuit round the outside of the cavity, either between the skin and muscles, or in the interval between the latter and the peritoneum; this deflected and circuitous route of the missile seems to have been produced more frequently by the old spherical bullet than is the case with the

modern conical one. Yet, according to Dr. Macleod (*Notes on the Surgery of the Crimean War*, p. 255), very many cases of this nature occurred in the Crimea. He says, "The strong aponeurosis which protects the front of the abdomen, exercises a great influence in deflecting the ball when it has struck at all obliquely. The track which is thus made requires careful management during cure, to get it to close. If it be long, it is good practice to make a counter-opening at its centre, in order to prevent the lodgment of pieces of cloth or pus in its interior. This can, however, be necessary only when, neither by syringing, nor by the introduction of an elastic bougie, we can get rid of them." When balls lodge in the parietes and are deeply seated, Mr. Guthrie recommends that they should be left alone, unless they prove troublesome; when superficial, they are to be extracted.

Wounds of the abdominal parietes slightly opening the peritoneum, should be united by suture, they are not generally followed in healthy subjects, by more than partial inflammation of that membrane; a sufficient amount is necessary to agglutinate the edges of the wound together; perfect quietude should be enjoined, and strict antiphlogistic treatment adopted. Mr. Guthrie recommends the avoidance of purgative medicines in such cases. No food, he states, should enter the patient's mouth, and only sufficient water to moisten his lips and allay the thirst. Injections of warm water and gentle laxatives may be administered after a day or two, to assist the operation of the bowels. The treatment should be regulated by the degree of inflammation which follows on the reaction; free venesection may be indispensable. Leeches are often very beneficial combined with bloodletting, or alone, where the patient's strength will not bear a larger abstraction. This treatment must be followed by calomel and opium every four or six hours, according to the urgency of the symptoms of each particular case.

The third order of wounds of the abdomen are perhaps the most fatal injuries that occur; of 63 cases reported under this head as occurring before Sebastopol, in men, subsequent to April 1st, 1855, only three recovered sufficiently to be invalided; in officers, 14 out of 15 died. The cause of death appears usually to have been from "shock" with or without internal hæmorrhage, and the great majority of the cases died within 24 hours of the receipt of the injury. The number of cases where serious hæmorrhage had taken place, either from vessels of the abdominal walls, or the contained great vessels or substance of the viscera, was considerable. A smaller proportion of the cases of penetrating gunshot wounds of the cavity died from peritonitis, usually of an asthenic form, and these often lived many days.

The most significant symptoms of lesion of the viscera are great prostration, weak and feeble pulse, tension of the abdomen, hiccough and vomiting; most if not all of these may occur in cases where there is no injury to the viscera, but the continuance of these symptoms indicates the very great probability of their being wounded. Where balls enter the peritoneal cavity without inflicting injury to the intestine, they may afterwards find their way into some portion of the canal by ulcerative absorption, and be eventually voided per anum: many instances of this nature are recorded; Baron Larrey,

however, states that in more than a hundred cases of this accident he had not observed a single example where a ball had been expelled by stool. He therefore advises that search should be made for the bullet with the finger and thumb, and removed if within reach.

Wounds of the small intestines are always considered to be more dangerous than the large. Dr. Thomson only saw two cases of wounds of the small gut, in the way of recovery, after Waterloo. Larrey reports several. The small intestines may be perforated in several places by the same bullet. A case of this kind occurred before Sebastopol, in the 19th Regiment, where the convolutions were wounded in sixteen places.]

It is observed by John Hunter, that such wounds of the abdomen as do not injure parts like the stomach, intestines, bladder, ureters, gall-bladder, large blood-vessels, &c., all of which contain particular fluids, will generally end well. But he adds, that there will be a great difference, when the ball has passed with immense velocity, as a slough will be produced; whereas, when the ball has moved with less impetus, there will not be so much sloughing, and the parts will in some degree heal by the first intention. Even when the ball occasions a slough, the wound frequently terminates well, the adhesive inflammation taking place in the peritoneum, all round the wound, so as to exclude the general cavity of the abdomen from taking part in the inflammation. Such is often the favourable event, when the ball, besides entering the abdomen, has wounded parts like the omentum, mesentery, &c., and gone quite through the body. (*Hunter, On Inflammation, Gunshot Wounds, &c.* p. 543.)

In gunshot wounds of the belly, an extravasation is apt to take place on the sloughs becoming loose, about eight, ten, twelve, or fourteen days after the accident; but, says Mr. Hunter, although this new symptom is in general very disagreeable, most of the danger is usually over before it can appear.

The stupor, that remarkable consequence of severe injuries, is particularly observed to follow those affecting the cavity of the abdomen. The patient quickly turns yellow, and lies completely motionless, inattentive to everything around him. (See *Dupuytren, Clin. Chir.* t. ii. p. 543.) This I have often seen exemplified in fatal cases.

At the assault of Cairo, 1799, M. N. was shot in the abdomen with a ball, which divided the muscular parietes of this cavity on the right side, and a portion of the ileum. Larrey being upon the field of battle, gave him the first assistance. The two ends of the intestine protruded in a separated and inflated state. The upper end was everted, in such a way, that its contracted edge, like the prepuce in a case of paraphimosis, strangulated the intestinal tube. The course of the fæces was thus obstructed, and the contents of the bowel accumulated above the constriction.

Although the patient's recovery was nearly hopeless, both from the nature of the wound, and from the debility and cholera morbus which had already seized him in the short period that he remained without succour in one of the intrenchments, Larrey was desirous of trying what could be done for so singular a case. He first made four small cuts through the constricted part of the intestine, with

a pair of curved scissors, and put the bowel into its ordinary state. He passed a ligature through the piece of the mesentery corresponding to the two extremities of the bowel. These he reduced as far as the margin of the opening, which he had taken care to dilate; and the dressings having been applied, he awaited events. The first days were attended with alarming symptoms, which, however, afterwards subsided. Those which depended upon the loss of the alimentary matter, successively abated; and, after two months, the ends of the ileum were opposite each other, and disposed to become connected together. Larrey seconded the efforts of nature, and dressed the patient with a tampon, or sort of tent, that was occasionally employed for two months. The patient was then discharged from the hospital quite cured.

In several instances, says Larrey, the sigmoid flexure of the colon was injured, and yet the wounds were cured without any faecal fistulae. At the siege of Acre, three examples occurred ; and,

at that of Cairo, two. Larrey dilated the entrance and exit of the ball. Clysters of the decoction of linseed, and emollient beverages, were frequently exhibited; and the patients were kept on low diet, and in the most quiet state.

[Wounds of the intestines sometimes remain fistulous for years, and then close.

Wounds of the stomach are followed by hic-cough, bloody vomiting and discharge of its contents, through the wound; they are very fatal. Baron Larrey calculates that four or five only out of twenty, survive. Mr. Alcock states that only one recovered in the Spanish Legion. In some of the recoveries fistulous openings have continued for years, or throughout life, as in the celebrated case of St. Martin.

Wounds of the spleen are rare; Larrey only saw three cases in his extended experience. The danger arising from them is primarily from hæmorrhage; and if the patient escapes this he may still succumb to fatal inflammation of the general peritoneal cavity.]

Wounds and injuries of the liver from blows or musket balls are very serious; when inflicted by grape, shell, or round shot, they generally soon prove fatal from hæmorrhage; when the result of a bullet, they are very generally unsuccessful, from the severe inflammation of the lining membrane of the cavity ensuing upon the injury. The symptoms are those of peritonitis super-added to those peculiar to the organ, viz. discoloration of the skin and urine, amounting to jaundice in some instances, pain in the shoulder and cramps; the discharge from the wound is either blood or bile, sometimes it is glutinous and tinged with bile, at other times it is serous or purulent. Wounds of the gall-bladder are nearly always mortal, from the effusion of bile into the peritoneal cavity giving rise to fatal inflammation. Recorded cases of recovery after this injury are rare.

Gunshot wounds of the kidney are scarcely less dangerous than those of the spleen. They are characterised by great pain in the lumbar region, bloody urine, retraction of the testicle, nausea and vomiting. Foreign bodies lodging in it may afterwards be expelled by the urethra. A very interesting case of this kind is narrated by Mr. Guthrie, attended, however, with great suffering. (*Commentaries*, edit. 6, p. 592—3.) The patient eventually recovered.]

In the article WOUNDS, I have detailed at large the general principles, which should be observed in the treatment of wounds of the belly; consequently it would be superfluous here to go over the whole of this extensive subject. As an excellent practical writer observes, "In their treatment, the violence of symptoms is to be combated more by general means, than by any of the mechanical aids of surgery. The search for extraneous bodies, unless superficially situated, is altogether out of the question, except they can be felt with the probe, as in Ravaton's case (*Chir. d'Armée*, p. 211). Enlargement or contraction of the original wound, as the case may require, for returning the protruded intestine, securing the intestine itself, and promoting the adhesion of the parts, are all that the surgeon has to do in the way of operation; and, even in this, the less he interferes the better. Nature makes wonderful exertions to relieve every injury inflicted upon her, and they are often surprisingly successful, if not injudiciously interfered with. In a penetrating wound of the abdomen, whether by a gunshot, or by a cutting instrument, if no protrusion of intestine take place (and this, it must be observed, in musket or pistol wounds rarely occurs), the lancet, with its powerful concomitants, abstinence and rest, particularly in the supine posture, are our chief dependence. Great pain and tension, which usually accompany these wounds, must be relieved by leeches to the abdomen (if they can be procured), by topical applications of fomentations, and the warm bath; and, if any internal medicine is given, as a purgative, it must, for obvious reasons, be of the mildest nature. The removal of the ingesta, as a source of irritation, is best effected, by frequently repeated oleaginous clysters" (see *Hennen's Principles of Military Surgery*, p. 431, ed. 3); and with respect to dressings, as the same author has observed, concerning cases in which a ball has passed directly through the abdomen, the mildest application should be employed, and no plugging with tents, nor introduction of medicated dressings, thought

of (p. 406). In this publication may be found cases, in which musket balls were passed by stool (p. 404); in which an artificial anus was formed, (p. 407, &c.); or the kidneys, liver (p. 430—432), diaphragm (p. 437), and other viscera injured.

[GUNSHOT INJURIES OF THE PELVIC CAVITY.]

[Wounds of this part of the body so often happen concurrently with injury of the peritoneal cavity, that they are classified and treated of under the head of abdominal injuries, as the danger of such wounds often depends upon this complication. Nevertheless, they sometimes occur alone, and render it necessary that they should be separately considered and described. Those occasioned by musket-bullets, where the soft structures only are concerned without including the osseous walls of this cavity, are not dangerous; but such injuries frequently lead to troublesome consequences, from the lodgment of balls giving rise to fistulous passages; the course of the bullet therefore should be carefully sought for, and if possible, it should be extracted. Injuries of this region, when produced by the larger missiles, such as grape-shot or large fragments of shell, are very severe, and often terminate unfavourably. A case of this kind occurred to me in the Crimean campaign, where the gluteus maximus was completely divided through its centre, and the great sciatic nerve severed, by a large portion of shell,—a most ghastly wound it was, attended with great suffering, and terminating fatally. When a bullet lodges near a bone, it sometimes occasions disease of its structure and derangement of the general health; at other times it becomes so deeply imbedded that it is never discovered, and remains during life. The close contact of a ball to a large nerve is followed by numbness, or even partial paralysis of the lower limb, accompanied with pain on change of weather, and obstinate costiveness. (*Hennen, Military Surgery*, ed. 3.) In some cases they give origin to periodical attacks of excruciating agony.

When the bones of the pelvis are broken, the injury is very serious, consequent on their deep position, neighbourhood to important structures, and thick covering. Sometimes balls pass through the pelvis and spare both bones and the contained viscera. Dr. Macleod speaks of a case where a bullet entered one sacro-ischiatic notch, and passed out of the other, without doing more mischief than contusing the rectum.

The cases of gunshot fractures of the bones of the pelvis which occurred before Sebastopol were usually found to be protracted and tedious, and where a fatal termination took place, it was almost invariably caused by sinking of the vital powers from long protracted and profuse discharge. Of twenty-seven cases which came under treatment, fourteen were fatal, and in two similar wounds which occurred in officers, both died. The amount and extent of the fracture, and the degree of displacement of the fractured portions, as well as the injury to the soft parts, were found to be very important elements in determining the probable result of such fractures. The strongest parts of the pelvis appeared to offer no adequate resistance to arrest the progress of the ball, and very frequently not even to turn it in any appreciable degree from its course, so different in this respect from the old spherical bullet. In the majority of

instances, but little appeared capable of being done in assisting nature beyond removing dead bone as it became loose, and careful attention to preserve a few outlets for the escape of suppuration. Dead bone often continued to present itself from time to time for many months after the receipt of the injury.]

When a ball passes through the pelvis, and breaks the bones, this latter circumstance alone constitutes a formidable accident; for, as Dupuytren observes, the bones are deep, covered by a thick mass of soft parts, and surrounded by considerable vessels and nerves. If the organs contained in the pelvis are wounded, the fluids or matters which are within them, are effused, inflammation ensues, and the result is mostly fatal. If large vessels are opened, the hæmorrhage cannot be stopped. If nerves are injured, paralysis of the rectum, bladder, or lower extremities, is the consequence. If the ball lodges in the thick substance of the bones, it is apt to bring on necrosis, periostitis, extensive and deep abscesses, sinuses, and fistulous openings. A wound of the bladder is followed by effusion of urine; one of the rectum, by that of fæcal matter; the dangers of which occurrences are great. (See *Dupuytren*, in *Clin. Chir.* t. ii. p. 544.)

[Wounds of the bladder are dangerous in proportion to the quantity of urine it contains at the time of the receipt of the wound, or as the upper and anterior or posterior and lower portion is engaged in the injury. Cases in which balls perforate that part of the bladder covered by peritoneum, almost always terminate fatally from the escape of urine into the peritoneal cavity, giving rise to general and violent inflammation of that membrane. Larrey states that all his patients died in the first forty-eight hours after the injury, and Mr. Guthrie describes them as rarely recovering, generally dying of inflammation and gangrene in from three to six days. (*Commentaries*, 6th ed. f. 603.) In the Crimean war, as far as I can discover by the returns, no case of this nature recovered. When the fundus is wounded at that portion where it is uncovered by peritoneum, the case admits of a cure, unless complicated with too much internal hæmorrhage.]

The surest criterion of these cases is the escape of the urine from the external wound; and its discharge may either be momentary, occasional, or continual; differences to be accounted for by the situation of the wound, and the changes which happen in the bladder. When the bladder is full, and its upper part is pierced, the urine will issue only just at the moment of the accident, and, as soon as it is discharged, the edges of the wound will come together, and permanently close, especially if the urine can pass freely through the natural channel. But when this favourable condition is absent, the bladder becomes enormously distended again, the wound is opened anew, and the urine discharged once more from the external opening. The same things might happen if one were to withdraw too soon the elastic gum catheter, which has been introduced; and by introducing the instrument again, the urine might be diverted from the wound, and its natural course re-established. Lastly, Larrey observes, that, when the wound is situated at one of the lowest points of the bladder, the discharge of urine may be incessant, and be of more or less duration.

When the track of these punctured wounds is extensive, and not direct, abscesses form at different points where the urine passes. These abscesses, Larrey directs to be immediately opened, and their recurrence prevented by the introduction of an elastic gum catheter through the urethra; one of the chief means of relief in all wounds of the bladder. Together with this treatment, he recommends the warm bath, the application of camphorated oily liniments to the belly, antispasmodic cooling medicines, frequent clysters, and sometimes cupping in the vicinity of the wound, or bleeding. (See *Mém. de Chir. Mil.* t. iv. p. 286, 287.) On the two last means of relief, it would have been better if Larrey had laid more stress; for, next to the catheter, they are unquestionably the most essential.

Baron Larrey informs us, that the gunshot wounds of the bladder, which occurred in Egypt, had for the most part a favourable termination. The most remarkable case was that of F. Chaumette, a light horseman, who was wounded at the battle of Tabor. The ball passed across the hypogastrium, about one finger's breadth above the pubes, to the point of the left buttock which corresponds to the ischiatic notch. The direction of the wound, and the issue of fæces and urine from the two orifices, left no doubt that the bladder and rectum were injured. M. Milioz, who directed the surgical affairs of the division of the army under Kleber, diligently pursued the same kind of treatment which he had seen Larrey adopt at the siege of Acre. During the suppurative stage, the patient was affected with fever; and, after the sloughs were detached, the discharge was very copious. A catheter that was passed into the bladder, prevented an extravasation of the urine, and at the same time promoted the union of the wound of that viscus. This was healed the first, and the patient, upon his return to Cairo, was quite cured.

Larrey has recorded several other interesting cases of wounds, either of the bladder alone, or of it and the rectum together, to which I must content myself with referring. (See *Mém. de Chir. Militaire*, t. ii. p. 160, 165; t. iii. p. 340, &c.; t. iv. p. 296, &c.)

A ball may go through both sides of the bladder, and then either perforate the neighbouring parts, and escape externally, or bury itself deeply in the flesh. When it has gone quite through the bladder, and afterwards passed out of the body again, urine, blended with blood, immediately issues from one or both apertures, according to their situation. The flow of urine through the urethra is either lessened, or completely suppressed; but, through this passage, the patient generally voids more or less blood. Acute and incessant pain is felt in the course of the wound, together with a frequent painful desire to make water, nausea, sometimes actual vomiting, and extreme anxiety and restlessness. Either in its passage inwards, or its course outwards, the ball may have injured or perforated the rectum; in which case, the urine passes into this bowel, and, mixing with the fæces, is discharged from the anus.

When a part of the bladder, towards the cavity of the abdomen, is injured, as, for instance, its posterior surface, which is covered by the peritoneum, the urine is generally extravasated within the belly, and inflammation of this serous membrane is the immediate consequence. This inflam-

mation spreads with rapidity, and attacks all the viscera, producing vast distension of the abdomen, fever, coma, and other bad symptoms, soon terminating in gangrene and death. (*Larrey, Mém. de Chir. Mil.* t. iv. p. 292, 293.)

During the first four-and-twenty hours, very little urine escapes from gunshot wounds of the bladder, in consequence of the swelling which almost instantly affects the lips of the wound. When the bladder is full, this fluid is discharged only at the moment of the accident, and mostly only from the wound by which the ball has made its exit. An extravasation is prevented by the thick slough which fills all the track of the injury, and it is not till the deadened parts become loose that any effusion can happen. Hence it is of the highest importance to introduce an elastic gum catheter into the bladder, where it should be kept, and the instrument should be large enough to fill exactly the urethra; for, according to Baron Larrey's observations, if, at the period when the sloughs are detached, the urine has not a ready passage outward, it passes through the wound, and is extravasated the more readily, inasmuch as the separation of the sloughs has occasioned many openings, by which the fluid may insinuate itself into the cellular membrane. Hence gangrenous mischief and death.

On two points my own experience would not lead me to join in the sentiments of Larrey: first, in opposition to his statement, I am sure that there is risk of extravasation of urine earlier than the period which he specifies, having known this accident commence within a few hours after the receipt of the wound; and therefore I should not depend upon the sloughs being always at first a complete barrier to extravasation of urine (indeed, their formation throughout the whole track of a gunshot wound is by no means a regular occurrence), but invariably pass a catheter as soon as possible, for the more certain prevention of this dangerous consequence. Secondly, the period of the separation of sloughs may indeed often be contemporary with the first appearance of symptoms of extravasation, particularly in cases where the employment of the catheter is for some time deferred, as in Baron Larrey's practice, because then a partial extravasation of the urine, soon after the injury, and previous to the introduction of the catheter, will cause rapid sloughing, and actually prevent the adhesive inflammation from closing up the cavities of the cellular membrane in time to prevent a fatal extension of that irritating fluid amongst the surrounding parts. Were it not for the partial early effusion of urine, no doubt, the adhesive inflammation would, in these cases, soon have the same effect, in obviating the danger of urinary extravasation, which it has after lithotomy, or paracentesis of the bladder. (See **BLADDER**.)

It is the practice of Baron Larrey to dilate the wounds, in order to facilitate the escape of the urine, which might otherwise lodge in the track of the ball; and perhaps, here the method may frequently be right, though I should conceive its propriety must usually depend upon whether the urine has a tendency to continue to flow out through the wounds or not, and upon the presence of obstruction or not. And, in confirmation of this opinion, I may cite Dr. Hennen's declaration, that, in these cases, he has very rarely found it necessary to enlarge the wound, when the catheter and

proper dressings have been employed. (*On Military Surgery*, p. 421, ed. 3.) As soon as possible, a large elastic gum catheter should be introduced, and left in the urethra, taking care to withdraw it, and pass in a clean one every two or three days, so that no incrustations may occur. Sometimes, however, the passage of a catheter is very difficult, as is the case when there are splinters of bone in the urethra, or the parts about the neck of the bladder are inflamed. (*Mém. de Chir. Militaire*, t. iv. p. 294.) Emollient clysters, and acidulated demulcent drinks, are to be prescribed, and the patient is to be kept upon a very low regimen, and in the most quiet state. The dressings are to be light and simple, and cleanliness observed. (*Op. cit.* t. ii. p. 165—170.) Instead of camphorated embrocations to the abdomen, another means commended by Larrey, it appears to me that this author's directions would have been more complete and judicious had he advised in these cases bleeding, both topical and general.

From the injury of arterial ramifications or varicose vessels, blood is sometimes extravasated within the wounded bladder, and causes deep-seated irritation. According to Baron Larrey, the case is indicated by the symptoms of retention of urine, and those of inflammation, with a small pulse, pallor of the countenance, and dryness of the wounds. (*T. iv.* p. 295.) A more decided criterion, I should think, would be the partial escape of urine mixed with blood, a symptom which could deceive only where the urethra itself had been injured. Larrey states, that blood, extravasated in the bladder, rarely coagulates, because blended with urine, and hence he advises its discharge to be facilitated by means of a catheter, and tepid, emollient, anodyne injections. (*T. iv.* p. 295.)

[In reference to this point, Mr. Guthrie states that the blood coagulates with equal proportions of urine, and recommends the introduction of a silver catheter, to break up the clots, and this to be followed by the injection of warm water, to assist in its solution. (*Commentaries*, edit. 6. f. 604-5.)]

Sometimes, balls carry before them into the bladder, fragments of bone, portions of clothing, small coins, pieces of buttons, &c.; or bits of bullets break off, and lodge in that viscus. When these extraneous bodies are not above a certain size, they are frequently voided through the urethra (see cases in Hennen's work, p. 419, 422, 424, &c. ed. 3.), and their evacuation may be materially facilitated by the introduction of an elastic gum catheter, the size of which is to be increased gradually, until the largest can be passed, when the foreign substances will readily enter the tube, or pass out through the dilated urethra. In this way, Baron Larrey has saved patients from a vast deal of suffering. (*Mém. de Chir. Mil.* t. iv. p. 302.) In such cases, the urethral forceps, made by Mr. Weiss, might often be used with advantage. (See **LITHOTOMY**.) When the ball is too large to be taken out in this manner, the lateral operation is to be performed, and it ought to be done before the bladder falls into an ulcerated or gangrenous state, from the pressure and irritation of the foreign body. However, as wounds of this organ frequently give rise to dangerous inflammation, Larrey recommends this operation to be done either before its attack, or after its subsidence. (*Vol. cit.* p. 309.) In fact, almost all the opera-

tions of this kind on record have been done some considerable time after the receipt of the wound, and to this practice my own judgment would lead me to give a general preference. In one case, however, Larrey operated on the fourth day after the receipt of the wound, and with success.

[Balls after remaining in the bladder some time get encrusted with the triple phosphates; the same deposit forms on pieces of bone which are driven into it, and which become the nuclei of calculi. It even forms on the coats of the bladder in the seat of the wound, and these crusts are afterwards detached.]

After the battle of Waterloo, I was not a little surprised to find, in the hospital established in the St. Elizabeth Barracks, at Brussels, a considerable number of cases in which either the intestines, the stomach, the omentum, or the bladder protruded. I think we had, in the division under Mr. Collier and myself, not less than three protrusions of the bladder. An order, which I received to join the army in the field on the 27th of June, deprived me of the opportunity of witnessing the progress and termination of these interesting cases. However, many had ended fatally before my departure from Brussels.

[Paralysis of the bladder is not an uncommon result of blows from shot or large pieces of shell, and rupture of the bladder when in a state of distension may occur, without being accompanied by corresponding injury to the external parts.

The rectum is sometimes wounded alone. Musket-balls occasionally lodge in this canal, and are afterwards passed per anum.]

[GUNSHOT WOUNDS OF THE PERINÆUM AND GENITO-URINARY ORGANS.]

[Wounds of the perinæum in which the bladder remains uninjured are not generally very serious, and eventually do well. In wounds of the scrotum where the tunica vaginalis is laid open, the testis, during the healing process, has a tendency to protrude. Many cases of this nature occurred before Sebastopol, and gave but little trouble in their management. Extensive protrusions of the substance of the testicle, or of fungous growth from it, do not appear to have occurred, and judiciously applied pressure seems always to have sufficed for the cure where any amount of protrusion had taken place. (*Medical and Surgical History of the British Army in Turkey and the Crimea*, p. 335.) Balls lodging in the testis must be removed; severe inflammation of this organ follows, and abscesses may form within the tunica vaginalis, and continue open for several weeks, but in the end terminate favourably. In these cases, where the testis is much bruised and shattered, it may be necessary to remove it to accelerate the cure; and Mr. Guthrie states that he has been obliged to extirpate it at a later period, in consequence of the wounded portion becoming enlarged and diseased, but, he observes, this occurrence is rare. In one case to which he refers the lodgment of a shot gave rise to enlargement which could not be distinguished from medullary sarcoma, and rendered the removal of the testis necessary; the patient afterwards died of disease of the lumbar glands. (*Commentaries on the Surgery of the War in Spain*, &c. p. 594.) Even slight wounds of the testis may lead to its ultimate absorption.

Wounds of the spermatic cord are rare, and seldom lead to fatal, although often to inconvenient, consequences.

The great toughness of the fibrous coverings of the erectile tissue of the penis appears to render perforation of its substance difficult. In a case which occurred at Sebastopol, a musket-ball entered between the glans penis and foreskin, ran under the skin the whole length of the organ without wounding the erectile tissue, and made its exit at the root of the penis, afterwards perforating the scrotum and entering the thigh, and was finally cut out of the buttock. Another very similar case is related, where the ball made its escape at the root of the organ on the opposite side of the penis to which it entered, and subsequently inflicted a wound in the thigh. (*Med. and Surg. History of the Army in the Crimea*). Mr. Guthrie states he had never any occasion to tie an artery, even when the penis was nearly amputated by the missile. "If bleeding should take place in the progress of the cure, a large catheter should be introduced into the urethra, as a point on which pressure may be made laterally; for I am not aware of any other use it can be, unless the urethra be also torn, when a moderate-sized catheter should be kept in it permanently, if it can be borne, to aid in the healing of the surrounding parts, with as little contraction as possible of the canal. When the corpus spongiosum has been carried away, or sloughs with the urethra, there is usually some injury done at the same time to the corpora cavernosa, and the part becomes contracted, and curved when distended. Several of these cases might be benefited by the formation of a new urethra by borrowing from the neighbouring parts after the practice recommended by Diefenbach." (*Commentaries*, p. 594-5.) A ball passing transversely through the corpora cavernosa causes little inconvenience, and the wound heals favourably. There is usually a deficiency of substance of the part after such wounds, and sometimes an inconvenient curve or twist during erection, such as often takes place when the corpora cavernosa and the corpus spongiosum are injured or ruptured from other causes. (*Op. cit.* p. 595.) Bullet or shell wounds where extensive laceration of the perinæum is produced, opening the urethra near the bladder, and causing extravasation of urine, will generally terminate unfavourably. Many of these present little or no chance of recovery from the commencement, and admit of but little aid from the surgical art. In all cases where the urethra is opened near the bladder, an attempt must be made to discover the opening, in order that an elastic gum catheter may be passed without delay into the bladder, so as to prevent or arrest extravasation of urine into the areolar tissue of the pelvis or perinæum. For this purpose the wound must be enlarged if necessary, in order to discover the opening into the urethra.

The perinæum may be extensively lacerated, and the bones of the pubis and ischium fractured, without any injury to the urethra, or scarcely any abrasion of the skin, as happened to a cavalry soldier at Goojerat by a round shot. The soft parts of the perinæum sloughed, but recovery took place.

In some cases of wound of the perinæum occurring at Sebastopol, partial or complete division of the sphincter ani was found to be necessary before the cure could be effected.

The following returns of gunshot wounds of the perinæum and genito-urinary organs without fracture of the pelvis or wound of the abdomen, from Sebastopol, occurring in men and officers, shows a considerable mortality; but the fatal cases were the result of large contusions and lacerations of the perinæum, involving the urinary apparatus, and chiefly inflicted by shell.]

GUNSHOT INJURIES OF THE HEART AND LARGE BLOOD-VESSELS.

[Wounds of the heart are almost always instantly fatal. Some rare instances, however, are recorded where recovery has followed even after severe lesions of this organ. The muscular structure has been perforated, and musket-balls have lodged in its substance, and cicatrices have been discovered after death in persons known to have been wounded in its vicinity, which indisputably show that very considerable lesions of this structure are not necessarily fatal. The diagnosis of these injuries is difficult, and most generally little more than conjectural, but through the instrumentality of the stethoscope some light may be thrown on the nature of the injury.]

The symptoms of gunshot wounds of the heart are described to be fainting, palpitation, irregular movement, or total cessation of its action, coldness of the extremities, ghastliness of countenance, succeeded by great anxiety or sense of anguish, intermission or cessation of the pulse. Should the patient survive, and reaction come on, the pulse increases in frequency and force of beat; the anxiety is increased by pain of the part, which is sometimes intolerable. (*Guthrie, Commentaries*, ed. 6, p. 510.)

M. Fournier mentions (*Cas Rares, Dictionnaire des Sciences Médicales*) the case of a soldier who had a ball lodged in the right ventricle near its apex, and who survived six years, dying at the end of that period of another disease. For the first three years after the receipt of the wound he was harassed with palpitation. Chastenot, a French army surgeon, relates the case of a soldier, the right ventricle of whose heart had been penetrated by a bayonet, and who died at the expi-

ration of fifteen days, from mortification of the lower extremities, apparently the result of cold and languid circulation. At the post-mortem examination the lung, pericardium, and heart were discovered to be wounded, but there was no sign of effusion into the surrounding parts. In the 14th volume of the *Edinburgh Medical and Surgical Journal*, another case is related where the right ventricle was perforated to the extent of an inch in length near the origin of the pulmonary artery; the ball was found in the pericardium; the tricuspid valve had a circular lacerated opening in it. The recipient of this injury was a soldier who had been wounded in Spain, and died at Plymouth the fourteenth day after the injury. These are some of the extraordinary examples of wound of this organ which have been recorded; they are extreme instances of what nature can bear, and we must not suppose that such favourable results are often likely to occur.

Dilatation of the heart is said sometimes to be produced by blows on the back or sternum, and death may occur from the shock of a blow over the region of this organ.

Treatment.—If the injury is the result of a musket-ball, the wound must not be closed, although pressure may be made upon it for a time with a view to the suppression of the external flow of blood; although this succeeds, it is more than probable the hæmorrhage will continue internally, and lead to the death of the patient after much suffering, principally from the oppression caused by the escape of blood into the cavity of the chest. If the wound be a stab, the external opening may be accurately closed and the escape of blood prevented; but as the pressure of the blood in the pericardium is unequal to restrain the action of the heart, blood forced out through the opening fills the cavity of the pleura, and produces suffocation, unless from some accidental circumstance the aperture in the heart becomes obstructed, and the flow of blood thereby arrested. There can be no doubt of the propriety of closing the wound in the first instance, if the hæmorrhage be excessive and likely to endanger life; and the wound must be reopened after a time if the danger of suffocation be imminent. (*Guthrie's Commentaries*, 6th ed. fol. 511-12.) This was the practice pursued by Dupuytren with the Duc de Berri, the right ventricle of whose heart was wounded, and who died from loss of blood: it was found requisite to reopen the wound every two hours to prevent suffocation.

All extraneous matters should be removed from the wound where possible, and inflammatory symptoms subdued by general and local bloodletting, calomel and opium, and antimony. Auscultation and percussion are to be employed, and if the cavity of the pleura or pericardium should be found filled with blood or other fluid, it must be evacuated in order to give the patient the chance of life. Gunshot wounds of the large arteries are very generally followed by speedy if not instant death; rare exceptions, however, occur. The most remarkable instance perhaps of recovery after such injury is that recited by Guattani in his work *On Aneurism*, where a patient survived a wound of the aorta for eight years. Wounds of these large vessels pour out the blood so rapidly, especially the large arteries in the cavities of the body, that there is scarcely a chance of life, the victims of such injuries dying on the

field before assistance can be rendered. How these vessels escape being wounded sometimes is a source of surprise amongst military surgeons. This immunity from injury is partly due to the elasticity of their coats, but principally to the ready manner in which they can be pushed aside by the passing ball, owing to the loose areolar tissue which connects them together and to the surrounding structures. I had a case of this kind under my care during the Crimean war, where a bullet passed between the subclavian artery and vein without injury to either, at the point where these vessels pass over the upper edge of the first rib.

In cases where a round shot or sabre injures or divides a large vessel, such as the carotid or femoral artery, immediate death is almost always the consequence; some instances to the contrary, however, are related. Larrey mentions a case in his *Mémoires* where the external carotid was divided at its point of separation from the internal; a soldier immediately applied pressure with his fingers, and Larrey's bandages eventually saved him. Mr. Hennen speaks of an officer who was wounded in the carotid by an arrow, and who owed his life to similar assistance.]

Wounds of the main arteries of the limbs or neck usually require both ends of the divided vessel to be secured with a ligature, if pressure fails to arrest the hæmorrhage. A ligature on the femoral artery, however, may sufficiently check the current of blood through the popliteal artery to put a stop to hæmorrhage from a wound in it; and though such practice in some other cases of wounded arteries is inefficient, on account of the facility with which the blood passes through the anastomoses into the part of those vessels below the ligature (see ARTERIES), its general success, in gunshot wounds of the ham, is very encouraging, not only on account of the difficulties of taking up the popliteal artery itself (difficulties ably depicted by Scarpa), but because laying open the inflamed and diseased parts would frequently have a fatal termination. Dupuytren and Delpech, on the latter principle, have in several instances taken up the femoral artery for the stoppage of bleeding from the tibial arteries in compound fractures, and with complete success. In University College Hospital, I took up the popliteal artery for the suppression of repeated and profuse hæmorrhage from the posterior tibial artery, which had been divided in a lad, who, as he was cleaning a window, slipped, and his leg passed through the glass, and the posterior soft parts were divided down to the bone. As the bleeding ceased, the wound was dressed, but, in consequence of returns of hæmorrhage, the house-surgeon made several unsuccessful attempts to secure the ends of the artery, and the wound had at length assumed a formidable appearance, with considerable swelling and tendency to gangrene. I therefore preferred tying the popliteal artery. The result was entirely successful, no recurrence of bleeding having been experienced. At the same time, I would have surgeons always recollect the important difference between an aneurismal and a wounded artery; for as, in the first case, there is no outlet for the blood, the transmission of this fluid into the part of the vessel below the ligature may keep up a pulsation in the tumor, and retard the cure of the disease, but is attended with no risk of hæmorrhage; while the same free passage of the blood into the wounded portion of a large ar-

tery would give rise to dangerous bleeding; and hence the general necessity of applying two ligatures, one immediately above, the other below, the aperture in such a vessel. A single ligature on the brachial artery fails, as I had an opportunity of seeing in Holland, in a case of gunshot wound, where either that vessel, or the commencement of the radial or ulnar, gave way, on the loosening of the sloughs; and, as there was considerable swelling, œdema, and inflammation of the limb, threatening gangrene, the surgeon under whose care the patient was, deemed it right to perform amputation.

I should be sorry if these observations were to hold out any general encouragement of the wrong and dangerous practice of applying only one ligature above a wound in a large artery, or in any recent case of *false diffused* aneurism. The remarks delivered above are chiefly intended to refer to gunshot wounds of the ham, with injury of the popliteal artery, and hæmorrhage first breaking out several days after the receipt of the wound, when all the parts behind the knee are enormously swollen, and in a state of inflammation and supuration. Here the hope of avoiding any additional violence, or injury to the diseased parts behind the knee, may be a good reason for taking the chance of stopping the bleeding by a ligature applied to the femoral artery; a reason, however, which would not exist in the case of a recent wound of the popliteal artery with a knife. At the same time, I believe this means of checking the current of blood will not always suffice, and that occasionally either the dangerous expedient of cutting open the swelling in this diseased state of the ham, and of applying a ligature above and below the aperture in the popliteal artery, must unavoidably be encountered, or amputation performed. Why the first plan has answered in some cases, and not in others, may depend upon the size and condition of the wound, or opening in the artery, and, in examples of sloughing, upon the degree in which the tube of the vessel may have been closed by the adhesive inflammation. Some wrong conclusions may also have been made respecting the trunk of the vessel being wounded or opened, while in fact only a branch of it was concerned.

[In quoting the following remarks from the *Surgical History of the Crimean War* (p. 345), I would mention that they embody the acknowledged practice for all military surgeons to follow, and that the cases referred to by Mr. Cooper are exceptional ones. "When an artery is primarily wounded and bleeds, it is presumed no surgeon will now dispute the propriety of tying both ends of the vessel at the wounded point. The late Mr. Guthrie has, however, laid it down that this is not to be done unless it bleed, inasmuch as the hæmorrhage once arrested may not be renewed."

Gunshot wounds of arteries sometimes lay the foundation for false or varicose aneurism. Hennen records a case where this condition followed a wound of the femoral, and in the *Bulletin de la Faculté de Médecine* of Paris, another case is given in which it was the result of a wound of the carotid artery. A case occurred in the 4th Regiment before Sebastopol of wound of the profunda femoris, two inches from its origin, which was followed by the formation of an aneurism at the wounded point.

Wounds of veins of the extremities or neck, however large, may always be checked by properly ap-

plied pressure; in general they are easily managed, and the hæmorrhage controlled by pressure and position. The amount of bleeding from very large veins is sometimes very inconsiderable. In a case under my care before Sebastopol, in which the subclavian vein, near its origin, was perforated by a bullet, the hæmorrhage was very trifling, and the slightest pressure arrested it. Inflammation of the vessel followed, however, and the man eventually died.

A varicose state of the veins is apt to occur after gunshot wounds. Dr. Hennen gives several cases, and states that it not unfrequently happens.

TABLE showing the number and results of cases of Direct Injury to the Larger Arteries, not being at the same time cases of compound fracture, which came under treatment from 1st April 1855 to the end of the Crimean War, in Men and Officers.]

GUNSHOT INJURIES OF JOINTS.

[Amongst the great variety of severe injuries that are met with after an action, perhaps none possess more interest than wounds of the articulations, owing to the numerous successful operations which have been performed for their removal by the Germans in the Schleswig-Holstein campaigns, the French in Algiers, and ourselves recently in the Crimea.

These injuries are, however, seldom confined to the joint; they most usually implicate more or less of the cylinder of the bone as well; but even such lesions, which do not involve too great an extent of the shaft, may be suitable cases for excision, and some most successful operations of this nature have been performed. These wounds are in the present day somewhat shorn of their terrors, for they were looked upon by the old army surgeons as mortal; nevertheless they do form a class of cases entailing much anxiety on the surgeon who is called upon to treat them, as to the best proceeding to be adopted in the management of each particular case. Great triumphs have already been achieved, and by this great advance in operative surgery the science of our art has been elevated, and the possibility of preserving a limb, or portion of a limb, for the unhappy sufferer, must ever enlist our best exertions for its further improvement and extension if possible. Still happier results may yet be accomplished by a more careful selection of the cases, greater skill in their performance, and more judicious after-treatment.

The gravity of these injuries is not always manifest in the first instance; a slight wound may be, and often is, followed by quite as severe symptoms as in those cases where there is a more extensive original lesion of the joint. This forms one of the difficulties in determining what is the best line of treatment to be followed: one is loth to excise a joint for very partial injury of the bones and soft

structures, yet when inflammation is set up, and suppuration of the entire articulation is established, the case then often becomes quite as severe in its consequences as where the wound and destruction of the deeper parts were of much greater magnitude in the first instance. As a general rule, the danger of these wounds of joints will depend chiefly on the size and complexity of the articulation affected, the extent of the injury, and the period which has elapsed since the receipt of the wound. Wounds of the ginglymoid articulations are considered to be more severe than those affecting the ball and socket joints, chiefly from their greater extent and more elaborate construction. Larrey has remarked that tetanus often followed their injury.

Hip-joint.—Severe compound fracture of the head, neck, and trochanters, or of the head and neck of the thigh-bone, or of the neck and upper part of the shaft without fracture of the head, which latter is a much more common injury, the head of this bone not being often implicated in the fracture, are all suitable cases for excision. Mr. Guthrie expresses his opinion strongly in favour of this operation in preference to leaving the case to nature, or performing the more severe operation of amputation at the hip-joint. (*Commentaries*, ed. 5. p. 81.) Esmarch considers that excision of the head of the femur ought to be performed in preference to exarticulation, although the single case operated on in the campaigns in the Duchies terminated unfavourably, whereas, out of seven exarticulations, one, a healthy young soldier seventeen years of age, survived the operation. (p. 94.) The experience of the Crimea is in favour of its performance; of six cases operated on, one recovered, and it was supposed would have a tolerably useful limb; another, a case of my own, lived five weeks after the operation, and was doing well until suppuration of the knee-joint supervened. In all the before-mentioned cases a portion of the shaft of the femur was included in the excision, in my own case about one-fifth. Seutin removed as much as six inches of the shaft in one case. In comparing the results of this operation with exarticulations of the limb performed in the English army during the Crimean war, we find the whole of the latter terminated fatally, the longest surviving the operation only thirty-six hours. The French are stated to have had thirteen primary and secondary amputations at the hip-joint after the battles of the Alma and Inkermann, all of which ended unfavourably. Stromeyer recommends resection of the head of the femur even when the fracture barely extends into the capsule, as suppuration is sure to be set up in the articulation, and produce death by exhaustion.

The objection that has been made to excision of the head of the femur—that the limb is rendered useless after the operation, even if recovery takes place—can hardly be entertained with reference to this particular injury. Indeed, it may even be questioned whether absolute inutility of the limb is always the inevitable result of such operations. It is to be hoped that after a sufficient interval of time has elapsed to allow of consolidation of the parts, and the limb has been duly exercised, certain amount of motion, strength, and usefulness of the new joint may be regained. The true aspect in which this operation must be viewed, as has been remarked by Dr. Macleod, is, that, as far

as results at present inform us, it is the only one which affords a chance of saving life.

Excision of the knee-joint has seldom been performed by military surgeons, though it has been so repeatedly and successfully executed in civil life for disease. A single operation of this nature, a secondary case, was the only one attempted during the Crimean war, and this unfortunately ended unfavourably. The Germans, during the second campaign of the Schleswig-Holstein war, performed this operation once, and likewise with a fatal result. So that up to the present time military experience of this operation has been very small and very unsatisfactory. The following are cases which, under favourable conditions, require the performance of resection: where a bullet has entered the joint and slightly injured the bone, or where, besides an injury of the capsule merely, a slight grazing or contusion of the bone has taken place. Bullets lodging in the heads of the bones, after entering the capsule, with or without fracture of the articular ends of the bones, but not extending into the shaft, seem also suitable cases for resection. Stromeyer does not recommend resection of this joint for gunshot injury, as, according to him, it affords little hope, even under favourable circumstances, and because in the majority of cases it cannot be certainly known how much of the bone should be sawn off. (*Translation by Statham, p. 31.*) The principal objections which military surgeons have to its performance seem to be the long period necessary to effect a cure, the absolute necessity there is for the perfect repose of the limb, and the very careful treatment requisite during the healing process, all of which are seldom attainable in army practice.

Resection in the continuity of the femur was practised in three cases during the Holstein campaigns, and all were fatal. The great depth at which this bone lies, and the large muscles which surround it, render it very unsuitable for any operation of this nature. Dr. Macleod states that resections of the shaft of the femur were invariably fatal in the Crimea. Esmarch does not recommend excision for any of the smaller shafts of the hand and foot, as hæmorrhage may follow only to be controlled by amputation of the hand or foot. Resection of the ankle-joint has not to my knowledge been performed in military practice. Penetrating wounds of this joint, according to Dr. Macleod, "generally did well in the Crimea, although they required long treatment. Great attention was paid to keeping the articulation perfectly immovable, and to the enlargement of one or other of the wounds, so as to allow of the free escape of all discharges." Comminuted fracture of the astragalus, and, according to Mr. Guthrie, the lodgment of a ball in that bone at a great depth, which cannot be extracted, are both cases which call for the removal of that bone. Ablation of the os calcis may be requisite for the corresponding injuries of that bone. I have seen the half of this latter bone excised for comminuted fracture; the wound healed speedily, and left a good use of the foot. Should the injury include the astragalus and os calcis, both bones must be removed. Mr. T. Wakley has published a very interesting case of this kind from disease, where the patient walked well after the operation. The remaining bones of the tarsus may be removed in like manner for similar injuries. (*Vide Guthrie, op. cit. p. 101.*) Mr.

Statham has performed the operation of resection of the ankle-joint successfully for disease. He recommends the flaps to be so made as to fall naturally in place after the operation without the use of sutures, and is of opinion that the limb should never be moved from the splint during the progress of cure. He also enjoins good diet after the operation, and frequently prescribes stimulants as well. If diffuse inflammation comes on, he recommends the patient to be put on the best stimulating and nourishing diet, though the inflammation be at its height, at the same time that abstraction of blood, poultices, &c. are employed locally. Iron, acids, and quinine should be given to enable the patient to assimilate the food he swallows. (*Statham, p. 120.*)

Excision of the Head of the Humerus.—Fractures of the head of the humerus, or cases where a bullet perforates or lodges in it, the main blood-vessel and nerves being uninjured, are very favourable cases for resection. M. Baudens states that excision should be the rule here, and amputation the exception. Mr. Guthrie expresses a similar opinion. The experience of the surgeons of the Schleswig-Holstein war was very favourable to this operation. Out of 19 cases 12 recovered, and a more or less useful arm was preserved. In some of the cases the wound healed in from two to three months. Complete ankylosis occurred in none. Some of the patients could perform heavy work afterwards. In the seven fatal cases the resection was made at the period of highest inflammation, or when the patients had become affected with pyæmia. In eight cases which were left to nature without operation, three did not prove fatal, but at the end of six months amputation of the affected limb was still considered likely to be called for. In some of these resections as much as four or five inches of the shaft of the humerus was included, and in the majority of the successful cases a greater or less amount of the shaft was affected. (*Esmarch, translated by Statham, p. 65.*) Of the 14 cases published by Baudens, 13 recovered, possessing an imperfect ginglymoid joint, but with the loss of the rotatory movements of the shoulder. This able surgeon objects to the division of the long tendon of the biceps muscle in the operation, and the surgeons of the Schleswig-Holstein campaigns always preserved this tendon entire, although they did not consider its preservation absolutely essential to the future mobility of the limb, as shown by three cases where the tendon was torn away by the ball. On the cure being completed, the patient soon obtained free and voluntary use of the arm. (*Esmarch, p. 67.*)

The results of resections of the head of the humerus before Sebastopol were very satisfactory. Of 13 cases 12 recovered, and were sent to England; the remaining one died. Highly favourable results these, when we take into consideration that formerly all these cases would most probably have undergone exarticulation at the shoulder-joint.

Where the scapula is extensively injured, and the injury is accompanied with fracture of the head of the humerus, resection, according to Stromeyer, is not successful. A single case of this kind where excision was resorted to, before Sebastopol, had a fatal termination.

Resection of the Continuity of the Shaft of the Humerus.—Stromeyer is of opinion that extensive resections of the shaft of the humerus should never

be practised in fresh wounds; the attention, he says, should be confined to the extraction of fully loose sequestra, and to the removal by the saw of the sharp points of bone. I cannot find recorded a single case where any large portion of the shaft of the humerus was removed during the Crimean war. Dr. Macleod, however, mentions that several cases resulted very favourably where parts of the shaft of the humerus and bones of the fore-arm were excised. I removed as much as three and a half inches of that bone, including in the resection the upper half of the deltoid impression, in a case of very bad compound fracture caused by a fragment of shell. The bone was comminuted and split to rather more than that extent. The wound healed in the most perfect and rapid manner, and the case soon lost its compound character. This soldier was invalided to England, and afterwards discharged the service, and I saw him again at the end of a year with a but little shortened limb. There was almost perfect consolidation of the divided ends of the bone, and all the underhand movements of the arm had been restored, and he was obtaining a livelihood by breaking stones on the road.

Resection of the Elbow-joint.—Baudens was of opinion that resection should only be performed where one alone of the three joint ends is injured. It was recommended as a rule, in all cases where a bone in this joint was injured, by the surgeons in the Schleswig-Holstein campaigns. When the ulna alone was shattered, the corresponding portion of the radius was removed, but seldom more than the head of that bone except in cases where the ulna had been comminuted, when the neck was likewise excised. If the radius was comminuted below the neck, the fragments were extracted, and the uneven projections removed by the saw; the ulna was not sawn off at the same level, but a piece from the olecranon only was removed, as otherwise this protruded in a troublesome manner during and after the healing. As on the ulna depends especially the strength of the elbow-joint, it was not found necessary to saw this bone off so low as the radius. A very small portion of the trochlea humeri was excised; in many cases the humerus was untouched, the cartilage merely being shaved off by the knife. This latter proceeding, however, seemed to have no influence in the production of a more rapid recovery. (*Stromeyer*, p. 24.) In cases where the injury involved only the humerus, one or other condyle being shattered, the fragments were removed and the humerus sawn off at the place where the fissures nearly terminated. By this means nearly an inch in its length was preserved. A piece was still removed from the olecranon, though uninjured. A portion of the wound was then united by interrupted suture, the lower part being left open for the escape of the discharge.

Partial resection of the elbow-joint, according to Esmarch, was not followed by such good results as complete removal of the ends of all the bones entering into the formation of the articulation. We ought not, he says, "to be content with a partial resection of the wounded parts, for in my opinion it is indeed the extensive severing of the ligamentous apparatus of the joint which deprives the wound of its danger, and the less there is removed from the ends of the bones, the greater is the probability of ankylosis. Partial resection was twice tried, and although both cases terminated

favourably, yet their progress showed that such an operation is in no respect preferable to the entire division of the articular capsule, perfect ankylosis occurring in both cases, and the process of healing being far more tedious than in resection of the entire joint." The experience of the Crimea was in conformity with this opinion. Dr. Macleod says: "Partial resection—of which there were a good many cases—did not, I think, turn out, on the whole, at all so well as complete ones. They were more tedious, more liable to fail, and less satisfactory when they succeeded, than when the whole articulation was removed." Amputation of the arm had to be performed in two cases after partial resection of the joint, during the Crimean war: in one case, however, where the heads of the radius and ulna were fractured by a rifle-ball which passed across the joint, the broken fragments were removed, and the humerus left entire; the patient, at the end of three months, was discharged with a good joint, which admitted of considerable latitude of motion, and could sustain no small weight.

The resections of the elbow-joint were remarkably successful when considered alone, but still more so when compared with the results of amputation of the arm during the Schleswig-Holstein war. Of 40 resections 6 only died, while out of 54 amputations of the arm 19 terminated fatally. During the latter half of the Crimean war there were 20 resections of this joint, partial and complete, 3 of which died, whereas out of 102 amputations of the arm 27 died. It seems then clearly established by these results, that the preference should always be given to excision in this articulation, in every case where such a proceeding is possible. As to the extent of the shaft that can be removed along with the particular ends of the bone, Esmarch states that as much as four or five inches were taken away both from the humerus and ulna and radius, where they had been struck off by a bullet: in one case a piece of four inches in length was removed. (*Op. cit.* p. 81-2.)

In the treatment of these injuries after the operation, the most important point to attend to is securing to the patient the most absolute quiet and complete position. The arm is to be laid in the prone position upon a wooden splint, extending from the upper third of the arm to the fingers' ends, at an obtuse angle at the elbow of 140 degrees, and secured to it by a bandage. Esmarch recommends in the first instance cold, and afterwards warm, water dressing, and, when the suppuration diminishes, charpie and oil. After the wound is filled with granulation, and cicatrisation has commenced, the arm is to be carefully raised from the splint, and a flannel roller applied. Passive motion is to be commenced early, very limited at first, and to be increased gradually every day, in order to insure the usefulness of the arm. The general treatment as practised by the Schleswig-Holstein surgeons was strictly antiphlogistic. (*Esmarch*, p. 57.)

In the cases which were operated on during the campaign in the Duchies, the hand could be raised to the mouth before the wound was closed. Pyæmia was the cause of death in most of the seven failures. (*Esmarch*, p. 68.) Of the six operated on in the first twenty-four hours, two were fatal; on the third or fourth day, three were performed, with two fatal cases. Secondary operations after the full

occurrence of suppuration were performed ten times, with three fatal results ; so that the secondary resections were more favourable than the primary ones. The resections of the left elbow were most fatal ; six out of twelve died, and only one out of seven resected on the right side had an unfavourable issue.

Excision of the Carpus, Metacarpus, and Phalanges.—A musket-ball perforating the carpus may so fracture several of the bones, that either amputation of the hand or the removal of the broken bones by excision, may become necessary. Mr. Stanley, in one case of disease of these bones, took away all of them except the trapezium, and even divided the extensor tendons, which reunited, and left a remarkably good motion of the hand and fingers ; but in gunshot wounds such perfect and satisfactory results can hardly be expected, as more or less of the tendinous structures slough away, owing to the destruction of their vitality at the time of the injury. Bullets perforating the metacarpus will generally fracture two of these bones; in such

cases the shattered ends of the fracture may be excised with the forceps or sawn off, or the entire metacarpal bone, should the injury be sufficiently extensive to require it, may be removed. As before stated, Esmarch does not advise resection for any of the smaller shafts of the hand, owing to the fear of hæmorrhage after the operation. Langenbeck removes the ends of the metacarpal bone and head of the first phalanx, or the distal end of the second and whole of the third phalanx, leaving the nail: the patient recovers with a shortened but useful finger.

It should be our especial aim in all injuries of the hand to preserve as much as possible; a finger, or portion of a finger, will be infinitely more serviceable than any mechanical appliance we can afterwards adapt to the stump. In many of the injuries of the hand the integuments are so much lacerated and contused as to render them very unsuitable cases for any attempt at preservation ; under such circumstances we must of necessity have recourse to amputation.]

[TABLE showing the number and results of cases of Resection of Bones in the English Army during the Crimean War, from 1st April 1855 to the end of the War.]
Non-commissioned Officers and Privates.

	Total treated.	Died.	Recovered.	Discharged and re-admitted for amputation.
Head of Humerus	13	1	12	0
Head of Humerus and part of Scapula	1	1	0	0
Shaft of Humerus, 3½ inches	1	0	1	0
Elbow-joint	17	3	12	2
Upper articular end, Radius and Ulna	1	0	1	0
Head of Radius	1	0	1	0
Internal condyle of Humerus	1	0	1	0
Part of Carpus and Metacarpus	3	1	2	0
Head of Femur	6	5	1	0
Knee-joint	1	1	0	0
Lower end of Fibula	1	0	1	0
Os Calcis and part of Astragalus	1	0	1	0
Os Calcis	1	0	1	0
Total	48	12	34	2

[THE USE OF CHLOROFORM IN OPERATIONS FOR GUNSHOT WOUNDS.]

[This anæsthetic agent was very generally used for annihilating pain during the performance of severe operations, both by the French and English surgeons, in the recent war in the Crimea. The experience of the former has been by far the most extensive, and according to their published account its employment has been followed by more fortunate results than has been the case in the English army. M. Baudens states that it was administered more than twenty-five thousand times without one fatal case occurring; “son triomphe a été complet,” he remarks in reference to its great utility. In our own army it was employed in nearly every operation of magnitude in all except the 2nd Division,

and in that more than one half of the operations were performed under its influence. A prejudice seems to have existed in the minds of some one or two of the surgeons against its use, from having witnessed a fatal case in a soldier who had undergone the operation of amputation of the finger, and this seems to have been the only indubitable case attended with a fatal result which can be strictly charged to its account. Others have been referred to, but as they were all instances of very formidable wounds, it is difficult to determine whether the fatal issue was owing to the poisonous influence of this agent, or due to the severe depression and loss of blood following the injury. In serious wounds it appears to have been the impression of most surgeons of experience that chloroform has a sustaining property rather than otherwise,

and enables the sufferer to submit to the operation with better prospects of success than if he had not been brought under its influence; but, as I have already mentioned, some one or two surgeons who had obtained considerable experience in operative surgery in the field, were impressed with the belief that it had deleterious effects when employed during the depression ensuing upon severe injury, although their objection, I believe, did not extend to its use in other cases. (See *Proceedings of the Army Medical and Surgical Society, Lancet*, July 19, 1856, p. 78—80.) In the cases detailed in support of this view, there appears to be a want of careful discrimination between the effects of chloroform and the depression consequent on very dangerous operations, super-added to extensive injury and copious hæmorrhage. There can be no doubt that many of the tedious and painful operations, such as excision of joints, were much more readily, carefully, and safely performed in the passive condition of the patient induced by the agency of this drug, than if the operator had had to contend with the writhing and convulsive movements of the sufferer; and the absence of pain during the operation, and generally for some time after the return of consciousness, must place the patient in a better position for recovery than if he had undergone the exhaustion consequent upon the agony and excitement of the operation. Such certainly appeared to me to be its effects in all the operations I myself performed or witnessed by others, and these views are confirmed by the French, and by the large majority of the English army surgeons. We must not, however, be insensible to, or undervalue, the dangers arising from its use; great caution should be adopted in its administration, the recumbent posture should be especially enjoined, and a watchful attention kept up, both with regard to the pulse and respiration, as well as to the sufficient supply of atmospheric air to the patient during the inhalation. In these cases, where much blood has been lost, this caution becomes even more necessary, owing to its rapid absorption in such persons.

It seems hardly necessary to combat the objections put forward by some, that it favoured secondary hæmorrhage, and that its employment led to the production of pyæmia, as alleged by others: no sufficient proofs have been established to warrant such inferences.

"In the prolonged searches which are sometimes necessary for the extraction of foreign bodies, chloroform is useful, not only in preventing pain, but also in restraining muscular contractions, by which obstacles are thrown in the way of the extraction, which did not oppose themselves to the introduction of the body. Then much is gained in field practice by the mere avoidance of the patient's screams when undergoing operation, as it frequently happens that but a thin partition, a blanket, or a few planks, intervene between him who is being operated on, and those who wait to undergo a like trial. Thus, when, as after a general engagement, a vast number of men come in quick succession to be subjected to operation, it is a point of great importance to save them from the depression and dread which the screams and groans of their comrades necessarily produce on them." (*Macleod, Notes on the Surgery of the War in the Crimea*, p. 134-5.)

GUAIACUM. Many writers of the sixteenth century contended, that guaiacum was a true specific for the venereal disease; and the celebrated Boerhaave, in the eighteenth, maintained the same opinion. Mr. Pearson mentions, that when he was first intrusted with the care of the Lock Hospital, in 1781, Mr. Bromfield and Mr. Williams were in the habit of reposing great confidence in the efficacy of a decoction of guaiacum wood. This was administered to such patients as had already employed the usual quantity of mercury; but who complained of nocturnal pains, or had gummata, nodes, ozæna, and such other effects of the venereal virus, connected with secondary symptoms, as did not yield to a course of mercurial frictions. The diet consisted of raisins and hard biscuit; from two to four pints of the decoction were taken every day; the hot bath was used twice a week; and a dose of antimonial wine and laudanum, or Dover's powder, was commonly taken every evening. Constant confinement to bed was not deemed necessary; neither was exposure to the vapour of burning spirit, with a view of exciting perspiration, often practised; as only a moist state of the skin was desired. This treatment was, sometimes, of singular advantage to those whose health had sustained injury from the disease, long confinement, and mercury. The strength increased; bad ulcers healed; exfoliations were completed; and these anomalous symptoms, which would have been exasperated by mercury, soon yielded to guaiacum.

Besides such cases, in which the good effects of guaiacum caused it to be erroneously regarded as a specific for the lues venerea, the medicine was also formerly given by some on the first attack of the venereal disease. The disorder being thus benefited, a radical cure was considered to be accomplished; and, though frequent relapses followed, yet, as these partly yielded to the same remedy, its reputation was still kept up. Many diseases also, which got well, were probably not really venereal cases. Mr. Pearson seems to allow, that, in syphilitic affections, it may, indeed, operate like

a true antidote, suspending for a time the progress of certain venereal symptoms, and removing other appearances altogether; but he observes, that experience has evinced, that the unsubdued virus yet remains active in the constitution.

Mr. Pearson found guaiacum of little use in pains of the bones, except when it proved sudorific; but that it was then inferior to antimony, or ammonia. When the constitution has been impaired by mercury, and long confinement, a thickened state of the ligaments, or periosteum, or foul ulcers, still remaining, Mr. Pearson says, these effects will often subside during the exhibition of the decoction. He says, it will often suspend, for a short time, the progress of certain secondary symptoms of the lues venerea; for instance, ulcers of the tonsils, venereal eruptions, and even nodes. Mr. Pearson, however, never knew one instance in which guaiacum eradicated the virus; and he contends, that its being conjoined with mercury neither increases the virtue of this mineral, lessens its bad effects, nor diminishes the necessity of giving a certain quantity of it. He has seen guaiacum produce good effects in cutaneous diseases, ozæna, and scrofulous affections of the membranes and ligaments. (See *Pearson, On the Effects of various Articles in the Cure of Lues Venerea*, edit. 2. 1807.)

[It will be observed, that the virtues attributed to guaiacum in the preceding article are manifested chiefly in the treatment of the tertiary order of symptoms, or syphilitic cachexia, in which the iodide of potassium has of late years proved so eminently successful and almost superseded other remedies. As regards the failure of guaiacum to eradicate all cachectic symptoms, this want of power is shared with iodide of potassium, mercury, sarsaparilla, and all other remedial means. (See *SYPHILIS*.)]

GUMMA, a soft tumor, so named from the resemblance of its contents to gum. (See *SYPHILIS*.)

GUMS, INFLAMMATION AND ABSCESS OF. *Gumboil. Parulis.* Inflammation of the gums mostly arises from the irritation of carious teeth, but sometimes from necrosis of a part of the alveolar process, or from the splintering of it, occasioned by the extraction of a bad tooth. Sometimes it originates from exposure to cold, and in other instances from mechanical irritation. When the inflammation, arising from the irritation of a decayed tooth, cold, and some other causes, proceeds to suppuration, the case is then an abscess, here termed a *gumboil*. The treatment consists in making an early puncture for the discharge of the matter, and, after the subsidence of the inflammation, in extracting any bad tooth concerned in keeping up irritation. The mouth is to be frequently cleansed with an astringent gargle. If a fistula form in the gums, it is to be freely divided, and touched with the nitrate of silver, care being taken, however, before resorting to this measure, to remove any carious tooth, splinter, or dead portion of bone, which latter proceeding will, generally, supersede all necessity for laying open the fistula.

GUMS, TUMORS OF. A very common disease is a thickening of the gums at some particular point, which puts on the form of an excrescence, and generally assumes a hard callous nature. Some of these swellings are connected with the periosteum, or bone, and are disposed to acquire a

malignant character; frequently, after they have attained a certain size, the neighbouring part of the bone becomes altered and softened. Other tumors of the gums are merely excrescences from the fibro-vascular texture of these parts, not penetrating deeply, not connected with the bone, periosteum, nor sockets of the teeth, and not malignant. The excrescence of the gums then, termed *epulis*, is of very different character in different cases; but, as many tumors of the gums, apparently trivial at first, become fatal diseases in the end, if neglected in their beginning, the rule in surgery is to attempt their extirpation, before they have made considerable progress.

On this subject Sir Charles Bell has made some interesting remarks. "We see (says he) a small tumor of the gums, stationary for a long time, and claiming no attention, at last forcing its way into the bones of the face, filling up the cells and the cavities of the nose, pressing out the eyes, and rising at last upon the base of the brain itself," so as to destroy the patient. The worst diseases of the gums, according to Sir C. Bell, do not come from the irritation of a bad tooth. "We see a carious tooth, attended with ulcer and gumboil, and abscess in the jaw; with fungous tumor of the gums; even with necrosis of the jaw. We find the inflammation from the same source amounting in severity of pain to that of *tic-douloureux*. But these are of no account, compared in danger with this tumor of which I am treating. This more formidable disease begins when the adjoining teeth are apparently sound, and when we cannot trace it to any common source of irritation. This tumor first shows itself in a small hard prominence of the gum, shooting out betwixt two of the teeth; and the teeth being good is an unfavourable circumstance; for when they have become loose and are displaced, without being themselves diseased, it implies that the cause is deep, and not to be removed by pulling out the teeth. If the teeth be carious and originally in fault, we have a reasonable expectation of arresting the progress of disease by removing the teeth; but when, independent of the teeth, the tumor has its origin in the membrane of the fang, or in the socket, we cannot hope to extirpate the disease, without removing the whole system of parts," the tooth, the gum, and the adjacent portion of the jaw. (See *Sir Charles Bell's Surgical Obs.* p. 413, 8vo. Lond. 1816.) A perpendicular division of the alveolar process is to be made at a prudent distance from each side of the tumor, and to the requisite depth, with a fine saw, any teeth in the way of its action being previously extracted. Then, with a strong pair of forceps, the portion of bone, between the two fissures, is to be broken off. The bleeding, which is copious, may sometimes be stopped by compresses dipped in the tincture of muriated iron, but frequently requires firm and long-continued pressure with the hands of a succession of assistants, or even the actual cautery.

The soft and more superficial kinds of *epulis* may be extirpated with a scalpel, care being taken to let the excision be sufficiently free and deep, and then to scrape the alveolar process, or rub the bottom of the wound with nitrate of silver, which will generally stop the hæmorrhage, and lessen the chance of a return of the excrescence. When the disease recurs often, as it did six times in a case mentioned by John Hunter, the removal

of the parts must either have been imperfect, or the tumor cancerous, as happened in two examples which fell under his observation. (See *J. Hunter, On Natural Hist. &c. of the Human Teeth*, p. 188.)

GUTTA SERENA. A term said to have been first applied by Actuarius to amaurosis, or the species of blindness arising from a morbid state of the retina, or optic nerve. When the word is now employed, it usually denotes the complete form of amaurosis, or that in which the patient is entirely deprived of the power of discerning objects, or even the difference between light and darkness. (See **AMAUROSIS**.)

[**GUTTÆ.**—This term is applied to lotions used in diseases of the eye, which are intended to be dropped on to the surface of the conjunctiva; while collyrium signifies a lotion which is to be applied to the outer surface of the eyelids, or with which

the lids are to be bathed, a small portion only reaching the conjunctiva. (See **COLLYRIUM**.)

The following formulæ are in use at the Royal London Ophthalmic Hospital in Moorfields:—

H

HÆMATOCELE (from *αἷμα*, blood, and *κῆλη*, tumor). A swelling of the testicle, proceeding from, or caused by, blood.

The term has sometimes been applied to every kind of extravasation of blood about the scrotum and spermatic cord; but, at the present day, it is usually restricted by British surgeons to a collection of blood in the cavity of the tunica vaginalis. Extravasation of blood into the cellular tissue of the scrotum and spermatic cord, or within the structure of the testicle itself, Pott, however, arranges with hæmatocele. The swelling of a hæmatocele is generally pyriform, like hydrocele, but is distinguishable from it by its greater weight and firmness, its want of transparency, its obscure fluctuation, and its cause, which is usually a blow upon the scrotum, or an accidental puncture of some vessels of the testicle, or tunica vaginalis, in tapping a hydrocele. When the latter membrane has been long, or much distended by the serous fluid of hydrocele, it becomes thickened, and its vessels, especially those of its inner surface, enlarged, and even varicose. If one of these lies in the way of the instrument with which the hydrocele is tapped, it is of course wounded, and then the fluid, which is discharged, is deeply tinged with blood. Should the bleeding continue, after the evacuation of the hydrocele, the blood will accumulate in the cavity of the tunica vaginalis, and, in the course of two or three hours, the scrotum will again be considerably swollen. In one or two examples, I have known hæmatocele follow the tapping of a hydrocele with a lancet, or other sharp-edged instrument. Sir Astley Cooper has noticed this risk, as attending the plan of tapping a hydrocele with a lancet. (*On the Structure and Dis. of the Testis*, p. 212.) A gentleman in the Fleet prison took it into his head to tap his hydrocele with a kind of long spring-lancet of his own invention: the operation was followed by the rapid formation of a very large hæmatocele.

Sometimes one of the enlarged veins of the tunica vaginalis bursts of itself, after the fluid of a hydrocele has been discharged, and hæmatocele then comes on, as it were, spontaneously. According to Sir Benjamin Brodie, hæmatocele may arise from a diseased condition of the arteries. "This

is analogous to that which occurs in the brain, under the form of sanguineous apoplexy. There is a natural change, which takes place in the arteries of old persons; they become ossified in patches, and ulcerate; and I have known this to lay the foundation of hæmatocele." (See *Lond. Med. Gaz.* vol. 1831-32, p. 927.)

As Sir Astley Cooper observes, hæmatocele is often connected with hydrocele, and is a consequence of it. The latter disease frequently becomes complicated with hæmatocele from an accidental blow on the tumor, occasioning a rent in the tunica vaginalis. In one case, operated upon by Sir Astley Cooper, this membrane had been ruptured to the extent of between one and two inches. The same distinguished surgeon records the case of a gentleman, in whom hæmatocele arose, not from a blow, but from excessive bodily exertion. (*On the Structure, &c. of the Testis*, p. 213—215.)

Of all the causes of hæmatocele, a blow on the scrotum is the most frequent, and especially a blow from the pommel of the saddle in riding. I have known the disease produced, however, by external violence of different kinds; as by a fall against a piece of timber, by which the scrotum was violently struck. After such accidents, the scrotum will suddenly swell to double or treble its natural size. Every swelling, so produced in the scrotum by effused blood, is not invariably a collection of this fluid in the tunica vaginalis; for sometimes the extravasation is in the loose cellular tissue external to this membrane. Hæmatocele is to be distinguished from the latter case, partly by the oblong or pyriform shape of the tumor, its obscure fluctuation, its freedom from the common appearances of ecchymosis, and its presenting itself more on one side of the scrotum than the other; while an extravasation of blood in the cellular tissue generally is more diffused, produces a dark blue discoloration of the part, and conceals more or less both testes.

When hæmatocele occurs in combination with hydrocele, the blood is mixed with the serous fluid contained in the tunica vaginalis, and partially dissolved in it: if the quantity of blood be small, the solution is complete; but, in the opposite case, coagula are formed, which remain undissolved. (*Sir B. Brodie, ib.*)

In the dissection of some hæmatoceles, the tunica vaginalis is found excessively thickened; and the blood in it, whether coagulated or fluid, is of the colour of coffee. Sir Astley Cooper refers to a preparation at St. Thomas's Hospital, exemplifying the serious mistake of removing the testicle, while the true disease was merely hæmatocele. The tunica vaginalis was excessively thickened, and filled with coagulated blood of a brownish red colour. (Op. cit. p. 215.)

A negro died in St. George's Hospital, who had an enlargement of one testicle; but as it had occasioned little or no inconvenience, the surgeon had not been consulted. Sir Benjamin Brodie examined the part after the patient's death, and found a very large quantity of grumous blood in the tunica vaginalis, and at the back part a soft pulpy mass was seen, not at all resembling the testicle in structure, and only recognisable as such by its connection with the epididymis and vas deferens. Sir Benjamin Brodie conceives, that the changed state of the testicle had been occasioned by the pressure of a large quantity of blood. (See *Lond. Med. Gaz.* 1831-1832, p. 927.)

Hæmatocele is sometimes unaccompanied by pain: this is the case when the quantity of blood is small, and no inflammation present. Under other circumstances, the disease may be attended with excessive pain, and bring on abscesses, gangrene, and dangerous degrees of constitutional disturbance. This was exemplified in the person whom I have mentioned as having produced hæmatocele by plunging a large lancet into his own hydrocele, for the purpose of curing it himself. In this instance, which I visited with Mr. Bransby Cooper, if a free and prompt incision had not been made to discharge the matter and putrid blood, the patient would soon have lost his life by the violence of the constitutional disturbance. Sir Benjamin Brodie mentions a painter, who was in the habit of drinking to excess, and who, while climbing a ladder, was seized with pain in the testicle, and an enormous hæmatocele formed. In this patient, the symptoms at first were more nearly allied to mania than delirium.

If hæmatocele be occasioned by a blow, and not accompanied by hydrocele, and the quantity of blood in the tunica vaginalis be moderate, the treatment should consist in keeping the patient in the recumbent position, administering purgative medicines, and covering the tumor with a cold lotion, which will have the effect of checking any further internal bleeding. These means will prevent inflammation, and, after a time, the blood will probably be absorbed. Were the quantity of blood considerable, its pressure might cause an absorption of the testicle (*Sir B. Brodie*), or, at all events, it would be likely to excite inflammation, and have little or no chance of being dispersed: in such a case, therefore, the best practitioners agree, respecting the propriety of laying open the tunica vaginalis, and taking out the blood.

If hæmatocele be combined with hydrocele, and free from much inflammation, Sir Astley Cooper recommends making an incision into the tunica vaginalis, discharging its contents, and, without introducing any lint into the cavity, leaving the cure to be completed by the process of inflammation. (*On the Structure, &c. of the Testis*, p. 216.)

If, on drawing off a hydrocele, the contents are tinged with blood, Sir Benjamin Brodie allows

the fluid to collect again, and repeats theappings at intervals, until no blood is mixed with it. The injection may then be used with success. Should the quantity of blood be large, he regards the expectation of its being removed by absorption as hopeless, and, therefore, punctures the tunica vaginalis with a lancet, introduces a director into the opening, and then enlarges it with a scalpel.

Whoever has read the observations of Pott on this subject will know that the operation of laying open the tunica vaginalis, for the cure of hæmatocele, is sometimes followed by a severe attack of symptomatic fever, delirium, and even death. In unfavourable constitutions, the symptoms will generally prove serious, whatever be the mode adopted of dressing the wound, or the internal treatment. But now that the plan of introducing lint and other extraneous substances into the exposed cavity is abandoned, bad cases are far less frequent than formerly. The violence of the symptoms will generally depend upon the degree of inflammation in the parts, and the kind of constitution in which it occurs. If hæmatocele excite inflammation, the clots of blood putrefy, and a gangrenous suppuration follows, attended with an accumulation of sulphuretted hydrogen in the part, and most urgent danger. Here a free opening must be made without delay, the scrotum poulticed or covered with cold lotions, and the patient kept under the influence of the muriate or acetate of morphia.

Mr. Pott, in his account of hæmatocele, comprehends one species, which he describes as an extravasation of blood within the tunica albuginea.

I confess that no good reason appears for arranging cases of this kind with hæmatocele; for what are they but diseased testicles, which have been punctured, either on account of their seeming to contain a fluid, or really having within them cysts filled with a chocolate-coloured or other fluid, as I have seen in hundreds of instances of sarcocele? and whatever blood is discharged is not extravasated in the substance of the testis previously to the puncture, but issues as a necessary consequence of that proceeding.

Another species of hæmatocele, noticed by Pott, arises from the bursting of a branch of the spermatic vein, between the groin and scrotum, within the sheath of the cord. This, which is generally produced by great or sudden exertions of strength, feats of agility, &c. may happen to persons in the best health.

I cannot conceive that in any case of a mere rupture of one of the spermatic veins, it can ever be justifiable to tie the whole spermatic cord, and then perform castration, though Pott advises this plan, if the bleeding branch cannot be tied singly. Discutient applications, and an occasional purge, will almost always disperse the swelling; and if not, opening it, and taking out the blood, applying cold, or, if necessary, filling the cavity with lint, and using compression, would be, according to my humble judgment, the most judicious treatment.

With regard to the extravasation of blood in the loose cellular tissue of the scrotum, from blows on the part, and sometimes from lithotomy, castration, &c., I have seen it followed by suppuration and sloughing; but in general the effused blood is gradually absorbed, with the aid of discutient applications, leeches, fomentations, poultices, and saline purges. A surgeon should generally be reluctant to lay open the tumor, as, in many in-

stances, sloughing and severe symptoms have been the result.

[In hæmatocele of any standing, whether traumatic or spontaneous, it should be borne in mind that pathological changes will take place both in the tunica vaginalis and in the blood itself. The serous membrane may inflame, and transude lymph instead of serum; thus a false membrane may be formed, to which the fibrin of the extravasated blood may readily adhere, or the serous membrane may simply have its secreting surface so far changed as to permit of the fibrin attaching itself to it in the form of a false membrane. Be this as it may, the tunica vaginalis will occasionally become more or less thickened, and in some extreme cases to the extent of half an inch or more, so that, after being opened and its contents removed, it is unable to collapse. The extravasated blood in contact with the living tissues does not altogether lose its vital properties, but undergoes peculiar changes in colour, in consistency, and in organisation, producing a variety of appearances in the contents of the more or less thickened tunica vaginalis. The serous parts disappear by absorption, as well as a certain portion of the colouring matter of the blood; the plastic materials become more or less organised, forming layers of false membrane adhering to the tunica vaginalis, or arranged so as to form partitions and cells, giving rise to a honeycombed appearance in the interior of the cyst. These cells and compartments of the hæmatocele will be filled with fluids of various colour and consistency, derived from the blood and from the imperfectly organised membranous laminæ. The plan of treatment suitable to a hæmatocele of long standing differs widely from that which may suffice in recent cases. When the tunica vaginalis becomes thickened to the extent of five or six lines, neither tapping, injecting, nor incision alone will be of any avail. The diseased tissues are incapable of repair. The layers of false membrane, after incision, must be peeled off from the interior of the tunica vaginalis, and the original membrane only left, or, if this cannot be effected, the entire adventitious structures, together with the tunica vaginalis, must be removed by the scalpel or scissors. Fortunately the visceral portion of the membrane is rarely implicated in the thickening, so that the testis and epididymis may generally be left untouched. Should, however, the adventitious deposit be equally developed on the testis and epididymis, or should these structures have suffered disorganisation and atrophy, castration should be performed as the only procedure likely to be effectual. I lately operated on a case in St. Mary's Hospital, by removal of the thickened tunica vaginalis, together with its contents, leaving the testis and epididymis, which appeared sound in the midst of a diseased mass. The man speedily recovered.

As this case explains well the pathological changes which a hæmatocele undergoes, and the treatment required in an advanced state of the disease, I will give it in detail.

Charles B—, aged forty-five, was operated upon for hydrocele during the course of the year 1855 in University College Hospital, with apparent success. In about two years from the date of the operation, however, the complaint began to return. Some months after this, in November 1857, during a violent fit of cough-

ing, he felt something give way, and an extensive and alarming swelling suddenly made its appearance, affecting the scrotum, penis, and cellular tissue over the pubes. This swelling, from its suddenness and from the discoloration of the skin, was evidently occasioned by effusion of blood. The swelling was punctured by a trocar, and a considerable quantity of bloody fluid escaped, inflammation followed, and the tumor returned.

In December of the same year he was admitted under my care in St. Mary's Hospital with a large *pyriform* swelling in the scrotum on the left side, looking like a hydrocele. The upper narrow part of the tumor corresponding to the cord was separated by a slight constriction from the lower and more globular portion. On manipulation, it was found that the tunica vaginalis was thicker than in an ordinary hydrocele, and that the fluctuation was rather less distinct. Five ounces of a dark bloody fluid were drawn off. A sharp attack of inflammation followed the use of the trocar, accompanied by a return of the swelling. On the 6th of January 1858, all inflammation having subsided, the following operation was performed. An incision three or four inches in length was made in front of the tumor, through the superficial coverings of the testicle, into the tunica vaginalis. This membrane was found to be much thickened, varying in this respect from three to six lines in different parts. It was of a yellowish white colour, tough, and sufficiently firm to retain its form. Two or three ounces of a discoloured fluid escaped from its interior. The remainder of its contents appeared to consist of coagulable lymph undergoing organic changes, and arranged so as to form numerous soft partitions, resembling considerably the honeycomb appearance seen in severe and fatal cases of pericarditis. The interspaces between these partitions were filled with serum, more or less tinged by the colouring matter of the blood. Here and there a more decided oval or globular little collection of this fluid might be noticed, looking like a cyst in the process of formation. The whole of these half-organised contents of the thickened tunica vaginalis were readily turned out with the finger; there was no adhesion sufficiently firm to require the use of the knife. The thickened and emptied tunica vaginalis was then dissected away from the scrotum, and detached from the testis and cord at its line of reflection from these structures. The portion of this membrane left adhering to the tunica albuginea and to the cord, did not fortunately partake of the thickening which in so marked a degree affected the part removed. The testis itself was not harder than usual, nor did it exceed its natural size. The patient lost a good deal of blood during the operation, and again the next day from secondary hæmorrhage, by which he was much blanched and debilitated. A healthy suppuration, however, was soon established; the granulations springing from the testis gradually united with those from the scrotum, and the patient made a steady, but slow recovery. He was discharged cured on the 16th of March 1858.

The treatment to be adopted in the several states in which cases of hæmatocele may present themselves may be thus summed up. In recent cases the attempts at obtaining resolution by rest, by discutient lotions, and by support to the tumor, combined with antiphlogistic treatment, will often succeed. If this plan fail, and the blood remain

fluid without mixture with coagula, and no inflammatory symptoms be present, the case may be treated successfully by evacuation of the fluid, and by injection, as in hydrocele. Should coagula be present, so as to prevent evacuation by tapping, or should inflammation set in, threatening suppuration, the appropriate remedy will be free incision into the tunica vaginalis. When false membranes have formed, thickening the serous membrane to a slight extent only, provided the contents of the sac can be evacuated, injection after tapping will sometimes effect a cure. But when the serous membrane is so far thickened that it cannot collapse after being emptied, or when its contents are too solid to admit of escape by the trocar, then incision and removal of all the adventitious structures, leaving if possible the original membrane, will be necessary; and lastly, when this cannot be effected with safety to the testis and epididymis on account of their being too seriously implicated in the disease, castration must be had recourse to.]

Celsus and *Paulus Ægineta* are the best of the old writers on hæmatocele. For modern information, consult *Pott's Chir. Works*, vol. ii. *B. Bell*, On Hydrocele. *Flajani*, Collezione d'Osservazioni, &c. t. ii. *Richter*, Anfangsgr. der Wundarzn. b. vi. *Oslander*, in *Arnemann's Magazin für die Wundarzn.* b. i. p. 355: the patient died after an opening had been made in the swelling. *Follet*, in *Journ. de Méd. continué*, vol. xiii. p. 422: *Harris*, in *Mem. of Lon. Med. Society*, vol. v. *Sir B. Brodie*, in *Lond. Med. Gaz.* for 1831-32, p. 926. *Sir A. Cooper*, in *Obs. on the Structure and Dis. of the Testicles*, p. 209, 4to. Lond. 1830. HÆMATURIA. (See URINE.)

[HÆMITIS. A term applied by *Piorry* to signify *Inflamed Blood*. *The Croupy Crasis* (*Rokitansky*); *Buffy Blood*, *Ebullition*, *Commotion*, *Inflammation*, of the blood (*Galen*, *Boerhaave*, *Sydenham*, and the physicians and surgeons generally before the time of *Cullen*); *Hyperinosis* (*F. Simon*).

Fever, small-pox, plague, and many other diseases were attributed by many of the most eminent of the humoral pathologists to an inflammation of the blood. This opinion was founded, in a great measure, on the occurrence of the buffy coat, and the resemblance which blood drawn in these diseases often bears to the blood in active inflammation, as pleurisy, and in rheumatism. (*Sydenham*, *Op. c. ii. s. ii. iii.*) *Sydenham* considered that wine inflamed the blood. (*Op. c. iv.*) These observers were guided by the increased temperature, bright colour, and other physical appearances. Surgeons of the present day have the advantage of more accurate anatomical details, and also of chemical researches, the result of which has been to confirm the idea of an inflammation of the blood. Even with those who adopt "exudation," as part of the definition of "inflammation," the blood need not be excluded, since the cellular structure of the corpuscles implies nutrition and secretion, and the probability of pathological exudations. An inflamed state of the blood being generally attended with an increase of fibrin, and some objections existing to the term hæmitis, we have preferred treating of the surgical importance of this morbid condition under another head. (See HYPERINOSIS.)

Henry Ansell.

HÆMORRHAGE (from *αἷμα*, blood, and *ῥήγνυμι*, to break out). *Bleeding*. *Effusion*, or *loss of blood*.

This is doubtless one of the most important subjects in surgery. The fear of hæmorrhage retarded the improvement of our profession for ages; the ancients, ignorant how to stop bleeding, were afraid to cut out the most trivial tumor, or they did so with terror. They generally performed slowly and imperfectly, by means of burning irons or ligatures, the same operations which the moderns execute quickly and safely with a knife. If the old surgeons ventured to amputate a limb, they only did so after it had mortified, by dividing the dead parts; and so great was their apprehension of hæmorrhage, that they only dared to cut parts which could no longer bleed. (*John Bell's Principles of Surgery*, vol. i. p. 142.) But not only as a consequence of surgical operations, is hæmorrhage to be feared; it is also one of the most alarming accidents which the surgeon is called upon to relieve. "*Un sentiment naturel attache à l'idée de perdre son sang, une terreur machinale, dont l'enfant qui commence à parler, et l'homme le plus décidé, sont également susceptibles. On ne peut point dire que cette peur soit chimérique. Si l'on comptoit ceux qui perdent la vie dans une bataille, on verroit, que les trois quarts ont péri par quelque hémorrhagie; et dans les grandes opérations de chirurgie cet accident est presque toujours le plus formidable.*" (*Morand, Mém. de l'Acad. de Chir.* vol. v. 8vo.)

As the blood circulates in the arteries with much greater impetus and rapidity than in the veins, it necessarily follows that their wounds are generally attended with more profuse hæmorrhage than those of the latter vessels, and that such hæmorrhage is more difficult to suppress. However, as the blood also flows through veins of great magnitude with much velocity, bleeding from them, if they lie deeply, is frequently highly dangerous, and sometimes unavoidably fatal. When a large artery is wounded, the blood is of a bright scarlet colour, and gushes from the vessel *per saltum*; but, if the artery be of inferior size, the blood, which first spouts from it, does not issue *per saltum*; and it is not until the first gush has subsided, that the stream takes place in jets. (See *J. W. Earle*, in *Lond. Med. Gaz.* vol. xvi. p. 9.) The blood issues from a vein in an even unbroken stream, and is of a dark purple red colour. It is of great practical use to remember these distinguishing differences between arterial and venous hæmorrhage, because, though in both cases the oozing of blood may be equal in quantity, yet, in the latter instance, the surgeon is often justified in bringing the sides of a wound together, without taking further means to suppress the bleeding, while it might not be proper to adopt the same conduct, were there an equal discharge of arterial blood.

Dr. Jones has favoured the world with a matchless work on the present subject; and as one grand object of this Dictionary is to present a careful account of the principal improvements in surgical science, I shall first endeavour to make the reader acquainted with the more accurate doctrines first promulgated by this gentleman relative to the subject of hæmorrhage. Afterwards, the surgical means to be practised in different cases will be considered.

The walls of the arteries are divisible into three coats. The *internal one* is extremely thin, and transparent and smooth. [It is lined by a delicate tessellated epithelium, which gives it somewhat the appearance and character of a serous mem-

brane.] It is elastic and firm in the longitudinal direction, but easily torn by the slightest force applied in the circular direction. Its diseases prove that it is vascular, and probably possesses sensibility. The experiments of M. Manec shew, that it secretes an unctuous matter, which facilitates the course of the blood; another fact in confirmation of its vascularity. (See *Manec, Traité de la Ligature des Artères*, Paris, 1832, in fol.)

[The middle coat is the thickest, and is divided into two layers. The outer of the two is composed of the yellow elastic tissue, and is found more abundant in the large arteries, the middle coat of the aorta being formed entirely of this layer. The inner or muscular layer is constituted of organic muscular fibre, arranged circularly, and is found in the greatest quantity in the smallest arteries. In those of intermediate size only are the two layers manifest, holding the position we have assigned to them.] As the middle coat has no longitudinal fibres, *the circular fibres are held together by a slender connection, which yields readily to any force, applied in the circumference of the artery.* It easily gives way, whether the force is exerted in the direction of the diameter, or in that of the course of the vessel. (See *J. L. Sanson, Des Hémorrhagies Traumatiques*, p. 33.)

The external coat is remarkable for its whiteness, density, and great elasticity. It adheres to the middle coat by means of very fine reddish filaments, analogous to those which unite the middle to the internal coat, and it manifestly receives the *vasa vasorum*. (See *J. L. Sanson*, op. cit.) *When an artery is surrounded with a tight ligature, its middle and internal coats are as completely divided by it as they could be by a knife, while the external coat remains entire.* (Jones.)

If an artery be extended longitudinally, the internal tunic is first ruptured, and then the middle one; but the external coat will admit of being elongated to a great extent before it will be torn. If an artery is twisted, rents are formed in the internal coat, and next in the middle one; but it is difficult to produce a complete rupture of the external tunic. If an artery is struck and forcibly contused, or if it is surrounded with a tight ligature, its internal and middle coats are readily divided, but the external one still makes resistance. (See *L. J. Sanson, Des Hémorrhagies Traumatiques*, p. 33.)

In addition to these three coats, it would appear from the researches of M. Malgaigne, that in the aorta, and the large trunks derived from it, there is interposed between the internal and fibrous coats, one, which he has named *sclerous*, which renders the aorta stronger and more rigid than the pulmonary artery; and is the seat of various earthy, steatomatous, and cartilaginous formations, met with in the former vessel. It is certainly remarkable, that no good specimen of an ossification of the pulmonary artery has ever been noticed. (See *J. Lisfranc, De l'Oblitération des Artères*, p. 10.)

Besides these proper coats, all the arteries, in their natural situations, are connected, by means of fine cellular tissue, with surrounding membranous sheaths. *If an artery be divided, the divided parts, owing to their elasticity, recede from each other, and the length of the cellular tissue, connecting the artery with the sheath, admits of its retracting a certain way within the sheath.*

Another important fact is, *that when an artery is divided, its truncated extremities contract in a greater or less degree, and the contraction is generally, if not always, permanent.*

Arteries are furnished with arteries, veins, absorbents, and nerves; *a structure, which makes them susceptible of every change to which living parts are subjected in common; enables them to inflame, when injured, and to pour out coagulating lymph, by which the injury is repaired, or the tube permanently closed.* (See Jones, *On Hæmorrhage*.)

Petit, in 1731, first endeavoured to explain the means which nature employs for the suppression of hæmorrhage. He thought that bleeding from a divided artery is stopped by the formation of a coagulum of blood, which is situated partly *within*, and partly *without* the vessel. The clot, he says, afterwards adheres to the inside of the artery, to its orifice, and to the surrounding parts; and he adds, that when hæmorrhage is stopped by a ligature, a coagulum is formed above the ligature, which only differs in shape from the one which takes place when no ligature is employed. His theory leads him to recommend compression for the support of the coagulum.

In 1736, Morand published additional interesting remarks. He allowed, that a coagulum had some effect in stopping hæmorrhage; but contended, that a corrugation, or plaiting, of the circular fibres of the artery which diminish its canal, and a shortening and consequent thickening of its longitudinal ones, which nearly rendered it impervious, had some share in the process. He thought that the cavity of an artery might be obliterated, by the puckering, or corrugation, when *circular pressure, like that of a ligature, was made.*

Morand erred chiefly in his mode of explanation, and in his belief in the existence of longitudinal fibres, which no modern anatomists admit; for the *contraction and retraction* of divided arteries are indisputable facts, and, as Dr. Jones remarks, this does not affect the truth of his general conclusion, *that the change, produced on a divided artery, contributes with the coagulum to stop the flow of blood.*

Mr. S. Sharp (2nd edit. of *Operations of Surgery*, 1739) supported the same doctrine. "The blood-vessels, immediately upon their division, bleed freely, and continue bleeding, till they are either stopped by art, or at length contracting, and withdrawing themselves into the wound, their extremities are shut up by coagulated blood."

Pouteau (*Mélanges de Chirurgie*, 1760) denied, that a coagulum is always found after an artery is divided; and when it is, he thought it only a feeble subsidiary means towards the suppression of hæmorrhage. He contended, that the retraction of the artery had not been demonstrated, and could not be more effectual than a coagulum. His theory was, that the swelling of the cellular membrane, at the circumference of the cut extremity of the artery, forms the principal impediment to the flow of blood; and that a ligature is useful in promoting a more immediate and extensive induration of the cellular substance.

Gooch, White, Aikin, and Kirkland, all oppose Petit's doctrine of coagulum. The first blends some of Pouteau's theory with his own, by observing, that "when a small artery is totally divided, its retraction may bring it under the surrounding parts, and with the natural contraction of the

diameter of its mouth, assisted by the compressive power of those parts, increased by their growing tumid, the efflux of blood may be stopped."

White was convinced, from what Gooch had suggested, and Kirkland confirmed, that the arteries, by their natural contraction, coalesce as far as their first ramification.

Dr. Jones admits, that an artery contracts after it has been divided, and his experiments authorise him to say, that the contraction of an artery is an important means, but certainly not the only, nor even the chief means, by which hæmorrhage is stopped. When the artery is above a certain size, the impetuous flow of blood through the wound of the artery would resist the contraction of the vessel in such a degree, that the consequences would be fatal in almost every instance, were it not for the formation of coagulum.

Mr. J. Bell supposed, that when hæmorrhage stops of its own accord, it is neither from the retraction of an artery, nor the constriction of its fibres, nor the formation of clots, but by the cells of the cellular tissue which surrounds the artery being injected with blood. I must refer the reader to Dr. Jones's work for a complete exposure of the inconsistencies and absurdities in Mr. Bell's account of his own theory. (See p. 25, &c.) Dr. Jones concludes his criticisms on Mr. Bell with observing, that if this gentleman really mean to confine his doctrine of the natural means of suppressing hæmorrhage to the injection of the cellular tissue round the artery with blood, he dwells improperly on one of the attendant circumstances, to the exclusion of the retraction and contraction of an artery, and the formation of a distinct clot, all primary parts of the process.

The blood, besides filling the cellular tissue round the artery, also fills that which is at the mouth of the artery in a particular manner; for the divided vessel, by its retraction within its cellular sheath, leaves a space of a determinate form, which, when all the circumstances necessary for the suppression of hæmorrhage operate, is gradually filled up by a distinct clot. (Jones.)

Arteries of the fourth or fifth order, like those of the forearm and leg, have not any well-defined sheath; and hence the constantly greater difficulty of insulating small vessels than large. (See *P. Manec, De la Ligature des Artères*, p. 3.)

MEANS OF NATURE IN STOPPING BLEEDING FROM DIVIDED ARTERIES.

Dr. Jones has given a faithful and accurate detail of a series of experiments on animals, which demonstrate, "that the blood, the action, and even the structure of the arteries, their sheath, and the cellular substance connecting them with it," are concerned in stopping bleeding from a divided artery of moderate size, in the following manner:—"An impetuous flow of blood, a sudden and forcible retraction of the artery within its sheath, and a slight contraction of its extremity, are the immediate, and almost simultaneous, effects of its division. The natural impulse, however, with which the blood is driven on, in some measure counteracts the retraction, and resists the contraction of the artery. The blood is effused into the cellular tissue between the artery and its sheath, and, passing through that canal of the sheath which had been formed by the retraction of the artery, flows freely externally, or is extravasated

into the surrounding cellular tissue, in proportion to the open or confined state of the wound. The retracting artery leaves the internal surface of the sheath uneven, by lacerating or stretching the cellular fibres that connected them. These fibres entangle the blood as it flows, and thus the foundation is laid for the formation of a coagulum at the mouth of the artery, and which appears to be completed by the blood, as it passes through this canal of the sheath, gradually adhering and coagulating around its internal surface, till it completely fills it up from the circumference to the centre." (Jones, p. 53.)

The effusion of blood into the surrounding cellular tissue, and between the artery and its sheath, but, in particular, the diminished force of the circulation from loss of blood, and the speedy coagulation of this fluid under these circumstances, most essentially contribute, says Dr. Jones, to the desirable effect.

It appears then that a coagulum, which Dr. Jones calls the *external* one, situated at the mouth of the artery, and within its sheath, forms the first complete obstacle to the continuance of bleeding; and though it seems externally like a continuation of the artery, yet, on slitting open this vessel, its termination can be plainly observed, with the coagulum shutting up its mouth, and contained in its sheath.

No collateral branch being very near the imperious mouth of the artery, the blood just within it is at rest, and usually forms a slender conical coagulum, which neither fills up the canal of the artery nor adheres to its sides, except by a small portion of the circumference of its base, near the extremity of the vessel. This coagulum is distinct from the former, and is called by Dr. Jones the *internal* one.

The description given by Mr. Guthrie of this subject differs in some respects from that of Dr. Jones. The contraction of the divided end of the artery is alleged by Mr. Guthrie "to be confined, in the first instance, to its very extremity, so that the barrier, opposing the flow of blood, is formed by this part alone. This contraction, however, goes on increasing for the space of an inch, and the inside of this contracted inch of the vessel is filled up with an internal coagulum, which takes the shape of, and adheres to, the inside of the artery, rarely extending as far as a collateral branch, or, under almost any circumstances, beyond a couple of inches. (*On Dis. and Injuries of Arteries*, p. 247.)

The cut end of the artery next inflames, and the vasa vasorum pour out lymph or fibrine, which fills up the extremity of the artery, is situated between the internal and external coagula, and is somewhat intermingled with them, or adheres to them, and is firmly united all round to the internal coat of the vessel. Dr. Jones further states that the permanent suppression of hæmorrhage chiefly depends on this coagulum of fibrine; but that the end of the artery is also secured by a gradual contraction which it undergoes, and by an effusion of fibrine between its tunics, and into the surrounding cellular tissue; whereby these parts become thickened, and so incorporated with each other, that one cannot be discerned from the other. Should the wound in the integuments not heal by the first intention, the coagulating lymph, soon effused, attaches the artery firmly to the subjacent and lateral

parts, gives it a new covering, and entirely excludes it from the outward wound.

The same circumstances are also remarkable in the portion of the vessel most remote from the heart. Its orifice, however, is usually more contracted, and its external coagulum smaller, than the one which attaches itself to the other cut end of the artery. (*Jones, On Hæmorrhage, p. 56.*)

According to Mr. Guthrie's observations, the lower end of a divided artery is more prone to secondary hæmorrhage than the upper; and this he believes to be so much the fact, that, when hæmorrhage returns, after having been arrested for a period of four hours, it is in all probability from the lower end. This, he further observes, may always be known by the "*darker colour of the blood, and by its flowing out in a continuous stream*, in the same manner as water rises from a spring, and without an arterial impulse. The surgeon has no right to believe that the blood comes from the upper extremity of the artery, unless it is of a florid scarlet arterial colour, when it will usually rush out with force, if not with undisguised arterial impetus." The greater disposition to secondary hæmorrhage in the lower than in the upper end of the artery, is thought by Mr. Guthrie to depend upon the retraction and contraction of the former, being neither so perfect nor so permanent as in the latter; a statement at variance with that of Jones. He suspects, also, that the internal coagulum is in many instances altogether wanting, or very defective in its formation. (*See G. J. Guthrie, On the Dis. and Injuries of Arteries, p. 248.*) We have seen that Dr. Jones found the external coagulum smaller here than that which is formed over the mouth of the end of the artery nearest the heart. The darker colour of the blood from the distal end of the artery is ascribed by M. Sanson to its previous passage through the capillary vessels; and the fact, he says, was observed by John Hunter. (*Des Hémorrhagies Traumatiques, p. 45.*)

The impervious extremity of the artery no longer allowing blood to circulate through it, the portion which lies between it and the first lateral branch gradually contracts, till its cavity is completely obliterated, and its tunics assume a ligamentous appearance. In a few days the external coagulum, which in the first instance stopped the hæmorrhage, is absorbed, and the coagulating lymph effused around it, and by which the parts were thickened, is gradually removed, so that they resume again their cellular texture.

At a still later period, the ligamentous portion is reduced to a filamentous state, so that the artery is, as it were, completely annihilated, from its cut end to the first lateral branch; but, long before this final change is accomplished, the inosculating branches have become considerably enlarged, so as to establish a free communication between the disunited parts of the main artery.

As Mr. Guthrie observes, out of four or five inches of the artery, two or three will be impervious, and the remaining part very much contracted, although, perhaps, still permeable by a probe. The accompanying nerve, where there is one, has undergone a change, the very reverse of that of the artery, its cut extremity having become enlarged or bulbous, the nerve gradually diminishing upwards until it resumes its proper size. (*On Dis. and Inj. of Arteries, p. 248.*)

When an artery has been divided at some dis-

tance from a lateral branch, three coagula are formed: one of blood, externally, which shuts up its mouth; one of lymph, just within the extremity of its canal; and one of blood, within its cavity, and contiguous to that of lymph. But, *when the artery has been divided near a lateral branch, no internal coagulum of blood is formed.* (*Jones, p. 63.*)

The external coagulum is always formed when the divided artery is left to nature: not so, however, if art interfere, for, under the application of the ligature, it can never form. If agaric, lyco-perdon, or sponge be used, its formation is doubtful, depending entirely upon the degree of pressure that is used; but the internal coagulum of blood will be equally formed, whether the treatment be left to art or nature, if no collateral branch be near the truncated extremity of the artery; and, lastly, effused fibrine, which, when in sufficient quantity, forms a distinct coagulum, just at the mouth of the artery, will be always found, if the hæmorrhage be permanently suppressed. (*Jones, p. 74.*)

MEANS WHICH NATURE EMPLOYS FOR SUPPRESSING THE HÆMORRHAGE FROM PUNCTURED OR PARTIALLY DIVIDED ARTERIES.

The suppression of hæmorrhage by the natural means is sometimes more easily accomplished, when an artery is completely divided, than when merely punctured or partially divided. Completely dividing a wounded artery was one means practised by the ancients for the stoppage of hæmorrhage: the moderns frequently do the same thing, when bleeding from the temporal artery proves troublesome.

Dr. Jones has related many experiments, highly worthy of perusal, and which were undertaken to investigate the present part of the subject of hæmorrhage. He candidly acknowledges, however, that, in regard to the temporary means by which the bleeding from a punctured artery is stopped, he has but little to add to what Petit has explained in his third publication on hæmorrhage. (*Mém. de l'Acad. des Sciences, 1735.*) The blood is effused into the cellular substance, between the artery and its sheath, for some distance both above and below the wounded part; and when the parts are examined, a short time after the hæmorrhage has completely stopped, we find a stratum of coagulated blood between the artery and its sheath, extending from a few inches below the wounded part to two or three inches above it, and somewhat thicker, or more prominent, over the wounded part than elsewhere.

Hence, rather than say that the hæmorrhage is stopped by a coagulum, it is more correct to say, that it is stopped by a thick lamina of coagulated blood, which, though somewhat thicker at the wounded part, is perfectly continuous with the coagulated blood lying between the artery and its sheath. (*Jones, p. 113.*)

When an artery is punctured, the immediate hæmorrhage, by filling up the space between the artery and its sheath with blood, and consequently distending the sheath, alters the relative situation of the puncture in the sheath to that in the artery, so that they are not exactly opposite to each other; and, by this means, a layer of blood is confined by the sheath over the puncture in the artery, and, by coagulating there, prevents any further effusion of blood.

But this coagulated blood, like the external coagulum of a divided artery, affords only a temporary barrier to the hæmorrhage; its permanent suppression is effected by a process of reparation, or of obliteration.

Dr. Jones's experiments prove that an artery, if wounded only to a moderate extent, is capable of reuniting and healing so completely, that, after a certain time, the cicatrization cannot be discovered either on its internal or external surface; and that even oblique and transverse wounds (which gape most), when they do not open the artery to a greater extent than one fourth of its circumference, are also filled up and healed by an effusion of coagulating lymph from their inflamed lips, so as to occasion but little or no obstruction to the canal of the artery. The utmost magnitude of a wound, which will still allow the continuity of the canal to be preserved, is difficult to be learned; for, when the wound is large, but yet capable of being united, such a quantity of coagulating lymph is poured out, that the canal of the vessel at the wounded part is more or less filled up by it. And when the wound is still larger, the vessel soon becomes either torn or ulcerated completely across, by which its complete division is accomplished.

Béclard made a series of experiments upon dogs, whose arteries are said not to differ much from those of man, though *the impulse of the heart is not so strong, and the blood is more coagulable*—two circumstances which should be duly considered in applying any of the inferences drawn from such experiments to the human subject. "In his first experiment he pricked the femoral artery with a needle; the blood flowed, but soon stopped. On removing the coagulum it again flowed, but in a smaller stream: it gradually ceased to bleed, and finally stopped, though the coagulum was again scraped off. On examination of the artery, no trace of the cicatrix was found. Several similar experiments had the same result. In experiment four, he denuded the femoral artery, and made a longitudinal cut in it, from two to three lines. The lips of the wound were seen in contact during the diastole of the ventricle, and to be separated by a jet of blood during the systole. The blood was stopped by a coagulum; this was removed twice, and each time the blood flowed in a diminished stream, but the animal died. In experiment six he made the same incision, but did not detach the sheath from the artery, and the wound was left to nature. The hæmorrhage was not great; there was an infiltration of blood into the sheath, the size of an almond, which at the end of some days began to diminish, and disappeared in two or three weeks. On the limb being examined, fifteen days afterwards, a little white ridge was found adhering firmly to the artery and to the sheath, and completely closing the wound. In the interior there was a depressed longitudinal cicatrix of the breadth of the fifth of a line. *The canal was regular and pervious* through its whole extent.

"In experiments 7, 8, 9, he made transverse incisions of $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ of the circumference of the femoral artery, *separated from its sheath*: all the animals died. In experiment 10, he made a transverse incision through $\frac{1}{4}$ of the circumference, *without disturbing the sheath*. The bleeding was stopped by a coagulum, but, on the animal moving, it again flowed, and the dog died. But, in the next experiment of the same kind, the blood was stopped by

a coagulum, and the artery was closed by nearly the same process as in the 6th experiment. So complete was the cure, at the end of six weeks, that the external part of the artery did not show any mark of a wound, and the cicatrix was scarcely observable on the interior surface. In his 12th experiment, he cut one half of the circumference; the animal died; the same result followed in several similar experiments. In experiment 13, he cut $\frac{3}{4}$ of the circumference: after the animal was much reduced, the bleeding ceased, and the artery was closed in the same manner that it is when the section is complete.

"From these experiments, he concludes that wounds of the arteries of dogs are cured by nature, when they are only occasioned by a puncture or a longitudinal incision, whether the artery be denuded or not; but, when arising from transverse incisions, they are always mortal if the artery be laid bare. If the artery retain its sheath, and the wound be $\frac{1}{4}$ or $\frac{3}{4}$ of the circumference, it may be cured by the efforts of nature; but it is always fatal if one half of it be cut through." (See *Mém. de la Soc. Méd. d'Emulation*, t. viii. p. 569.) The inferences respecting the curability of a wound, extending through $\frac{3}{4}$ of the circumference, and the incurability of one that affects only one half of the circumference of the vessel, I should presume, must require further examination, notwithstanding an accidental faintness, produced by the sudden loss of blood in the first instance, may have been the means of saving one or two of the animals on which Béclard made his experiments.

This author thinks it probable that a puncture, or longitudinal incision, in the artery of a man, may be cured by nature; but that a transverse wound never cicatrises properly, as the clot becomes displaced, or, if a cicatrix be formed, it will be distended and torn.

One fact, made out by the same professor, is, that when an artery is deprived of its sheath for an extent greater than its distance of retraction, the hæmorrhage is mortal. I have not looked over the original paper; but it appears to me that it would be desirable to know precisely the size of the arteries which the author is referring to, when he is making some of the above inferences. The size and condition of each animal the subject of experiment, should also be particularly specified; as experiments made on the femoral artery of a lady's lap-dog would surely not have the same results as those performed on the same artery of a large terrier or Newfoundland dog.

According to Dr. Jones, the lymph which fills up the wound of an artery, is poured out very freely both from the vessel and surrounding parts, and it accumulates around the artery, particularly over the wound, where it forms a more distinct tumor. The exposed surrounding parts at the same time inflame, and pour out coagulating lymph, with which the whole surface of the wound becomes covered, and which completely excludes the artery from the external wound. This lymph granulates, and the wound is filled up and healed in the usual manner. (See *Jones, On Hæmorrhage*, p. 113, &c.)

SURGICAL MEANS OF SUPPRESSING HÆMORRHAGE.

It must be plain to every one who understands the course of the circulation, that pressure made on that portion of a wounded artery which adjoins

the wound towards the heart, must check the effusion of blood. The current of blood in the veins, running in the opposite direction, requires the pressure to be applied to that side of the wound which is most remote from the heart. However, on account of the freedom and facility with which the blood is transmitted through the anastomosing branches, from the portion of the artery above the point of pressure into the branches of the lower continuation of the artery, such pressure will often only check, and not effectually stop the bleeding, unless the part of the vessel directly below the wound be also compressed or secured. As pressure is the most rational means of impeding hæmorrhage, so it is the most effectual; and almost all the plans employed for this purpose are only modifications of it. The tourniquet, the ligature, the application of a roller and compresses, even agaric itself, only become useful in the suppression of hæmorrhage, on the principle of pressure: the cautery, caustics, and styptics, however, have a different mode of operation.

In order to prevent a wounded person from dying of hæmorrhage, Celsus advised the wound to be filled with dry lint, over which was laid a sponge dipped in cold water, and pressed on the part with the hand. If, notwithstanding these means, the hæmorrhage should continue, he recommends repeatedly applying fresh lint, wet with vinegar; but he is against the use of corroding escharotic applications, on account of the inflammation which they produce, or only sanctions the employment of the mildest ones. When the hæmorrhage resists these methods, *he advises two ligatures to be applied to the wounded part of the vessel, and then dividing the portion situated between them*:—"Quod si illa quoque profluvio vincuntur, venæ, quæ sanguinem fundunt, apprehendendæ, circaque id, quod ictum est, duobus locis deligandæ, intercidendæque sunt, ut et in se ipsæ coeant, et nihilominus ora præclusa habeant." (Lib. v. cap. 26.) When the ligature was impracticable, the wound bled dangerously, and no large nerves, nor muscles, were situated in the bleeding part, Celsus proposed the actual cautery.

Galen also mentions tying the vessels for the purpose of stopping hæmorrhage; and there are some traces of the same information in other authors who lived before him, as Archigenes and Rufus. Probably, however, the ligature was little used at these early periods, as may be inferred from the multitude of astringents, caustics, and other applications, which were advised for stopping bleeding, and in which less confidence would have been put, had the use of the ligature been familiarly known. No one can doubt that, if the old surgeons had had many opportunities of seeing the advantages of the ligature, they would soon have used it after amputations; but so far were they from adopting such practice, that Albucasis, a long while afterwards, refused to amputate at the wrist, lest he should see his patient bleed to death.

Paré is considered as the first who regularly employed the ligature after amputation. His method having been attacked, he modestly defends it in the part of his works entitled *Apologie*, where he takes great care to impute the origin of it to the ancients; and cites many of them, who had made mention of it. However, he thinks its utility in amputations of such consequence, that he ascribes

his first adoption of this practice to inspiration of the Deity.

The method, in which the ancients placed most confidence, for stopping hæmorrhage after the amputation of a limb, was the cauterisation of the cut vessel and surrounding flesh. The parts thus affected by the heat, formed an eschar of greater or less thickness, which blocked up the opening of the vessel, and hindered the blood from escaping. The separation of the eschar, however, which frequently took place too soon, occasioned a return of hæmorrhage, and rendered it the more dangerous, as its suppression was now more difficult than before the cautery had been applied. Sometimes the instrument, being too much heated, immediately brought away with it the eschar. At the present time, the cautery is never employed as a means of suppressing hæmorrhage, or, at most, only in a few very unusual cases, in which neither compression nor the ligature can be made use of. In Great Britain, the cautery is never employed, except in circumstances of this description; but in France, the best hospital surgeons now and then employ it to stop bleedings from the anus, antrum, and mouth.

The old surgeons very commonly applied to bleeding parts pledgets, dipped in boiling turpentine,—a practice that has long been most justly abandoned.

ASTRINGENTS, STYPTICS, &c.

Le Dran says, that a button of vitriol, or alum, applied and properly confined on the extremity of the vessel, is sufficient to stop the hæmorrhage in amputations. Heister recommends the application of vitriol, in preference to the ligature, in the amputation of the fore-arm. Great praises have also been conferred on agaric, and sponge, for their styptic properties. Solutions of iron, and all the mineral acids in various forms, have been recommended to the public, as remedies of the same kind, and possessing great efficacy. The ancients, centuries ago, left no application of this nature untried, and the pretended discoveries of new and more effectual styptics in later times, may almost all be met with in their writings. This fact merits particular notice, because the little success attending their practice, especially when bleeding from a considerable artery was to be suppressed, clearly proves what little reliance ought to be placed on means of this description. (*Encyclopédie Méthodique, Partie Chir.*) The most which styptics can do, is to stop hæmorrhages from small arteries; but they ought never to be trusted when large vessels are concerned.

[Perhaps the most efficient styptic is a saturated solution of the perchloride of iron, applied to and gently pressed upon the bleeding surface by means of a small piece of sponge or lint. This solution acts by promoting coagulation of the blood, as well as by inducing contraction of the blood-vessels. With this view it has been used as an injection in nævi and in varicose veins. (See NÆVUS, VARICOSE VEINS, &c.)]

There is no doubt that cold air has a styptic property; by which expression, I mean that it promotes the contraction of the vessels. We frequently tie on the surface of a wound every artery that betrays the least disposition to bleed, so long as the wound continues exposed to the air. We bring the opposite sides of this wound into

contact, and put the patient to bed. Not an hour elapses before the renewal of hæmorrhage compels us to remove the dressings. The wound is again exposed to the air, and again the bleeding ceases. This often happens in the scrotum, after the removal of a testicle, and on the chest, after the removal of a breast. The proper conduct, in such cases, is not to open the wound unnecessarily, but to apply pressure, or else wet linen, to the part, so as to produce such an evaporation from its surface as shall create a sufficient degree of cold to stop the bleeding. As all styptics are more or less irritating, no judicious practitioners apply them to recent wounds. However, for the suppression of hæmorrhage from diseased surfaces, where the vessels seem to have lost their natural disposition to contract, these applications are sometimes indicated.

COMPRESSION.

We have already remarked, that all the best means of checking hæmorrhage operate on the principle of pressure; the actual and potential cautery, and some styptics excepted: the two first of which act by forming a slough, which stops up the mouths of the vessels; while the latter operate either by promoting their contraction or by coagulating the blood. Let us next consider the various modifications of pressure.

In a dissertation on the manner of stopping hæmorrhage, printed in the *Mém. de l'Acad. des Sciences, année 1731*, Petit endeavoured to prove, that different articles, praised as infallible specifics, would seldom, or never, have succeeded without compression. Even when caustics were employed, it was usual to bind compresses tightly on the part, so as to resist the impulse of the blood in the artery, and the premature separation of the eschar. Had this precaution not been taken, Petit believes that hæmorrhage would almost invariably have followed; and, indeed, notwithstanding the pains taken to avert it by suitable compression, it did too frequently take place on the detachment of the eschar. Petit has noticed, that the end of a finger, gently compressing the mouth of a vessel, is a sufficient means of stopping hæmorrhage from it, and that nothing else would be necessary, if the finger and stump could always be kept in this posture. Hence, he endeavoured to obviate these difficulties by inventing a machine which securely and incessantly executed the office of the finger. The instrument was a double tourniquet, which, when applied, compressed at once both the extremity of the divided artery and its trunk above the wound. The compression on the end of the vessel was permanent; that on the trunk was made only at the time of dressing the wound, or when it was necessary to relax the other. An engraving and particular description of the instrument are to be found in Petit's memoir.

Surgeons formerly filled the cavities of wounds with lint, or charpie, and then made pressure on the bleeding vessels, by applying compresses and a tight roller over the part. The practitioners of the present day are too well acquainted with the advantages of not allowing any extraneous substance to intervene between the opposite surfaces of a recent wound to persist in the above plan. They know, that the sides of the wound may be brought into contact, and that compression may yet be adopted, so as both to restrain particular

hæmorrhages, and rather promote, than retard, the union of the wound.

When the blood does not issue from any particular vessel, but from numerous small ones, compression is preferable to the ligature. In the employment of the latter, it would be necessary to tie the whole surface of the wound. The sides of the wound are to be brought accurately together, and compresses are then to be placed over the part, and a roller to be applied with sufficient tightness to make effectual pressure, but not so forcibly as to produce any chance of the circulation in the limb being completely stopped.

If, in bleeding from large arteries, compression can ever be prudently tried, it is when these vessels lie immediately over a bone. Bleedings from the radial and temporal arteries are generally cited as cases of this kind, though, from the many instances of failure which I have seen happen where the first of these vessels is concerned, I should be reluctant either to advise or make such an attempt. Compression is sometimes tried, when the brachial artery has been wounded in phlebotomy. Here it is occasionally tried, in preference to the ligature, because the latter cannot be employed without an operation to expose the artery.

"When the brachial artery has been wounded, in bleeding at the bend of the arm (says Mr. Crosse), I find so many instances narrated of successful management by pressure, that it seems imperative on us to regard this as the general rule of treatment. Sometimes the artery has been extensively obliterated by the pressure employed; at others, the same change has taken place in the vein; and one example is afforded of the aperture between the artery and the vein closing, each vessel remaining pervious after the cure. Pressure is, however, applicable only where a competent surgeon has the opportunity of employing it soon after the injury" (*J. G. Crosse, in Prov. Med. and Surgical Trans.* vol. v.); and, I would add, while the quantity of blood, effused in the cellular tissue, is not such as to interfere with its operation, or to render the trial of it likely to bring on mortification.

When there is a small wound in a large artery, the following plan may be tried: a tourniquet is to be applied, so as to command the flow of blood into the vessel; the edges of the external wound are next to be brought into contact: then, a compress, shaped like a blunt cone, and which is best formed of a series of compresses, gradually increasing in size, is to be placed with its apex exactly on the situation of the wound in the artery. This *graduated compress*, as it is termed, is then to be bound on the part with a roller.

In this manner, I once healed a wound of the superficial palmar arch, in a young lady in Great Pulteney Street. The outward wound was very small; and though the hæmorrhage was profuse, I conceived, that it might be permanently stopped, if compression could be so made as to keep the external wound incessantly and firmly covered for the space of a day or two. At first I tried a compress of lint, bound on the part with a roller; but this proving ineffectual, I took some pieces of money, from the size of a farthing to that of a half-crown, and, wrapping them up in linen, put the smallest one accurately over the wound, so as completely to cover it. Then the others were arranged,

and all of them were firmly confined with a roller, and the arm kept as quiet as possible in a sling. They were taken off after three days, and no hæmorrhage ensued.

When the palmar fascia is not freely cut, it is conceivable, that it might prevent compression from operating on the vessel; but the foregoing case shows, that a wound of the superficial palmar arch is capable of healing, if the blood be completely prevented from getting out of the external wound by the proper application of compression. Were the outer wound free and open, it would be the safest practice to take up the ends of the vessel. Mr. Crosse, of Norwich, in more than one or two instances, has succeeded in tying the palmar arch when wounded, and would always *first* attempt it, going to another resource only when that had failed, or swelling and inflammation prevented it. He thinks it would be going a great length, to put a ligature on the brachial artery for a wounded palmar arch. (Op. et vol. cit.) Sometimes tying the ulnar artery has failed; but, under these circumstances, instead of tying the brachial artery, if the state of the wound would not bear pressure, I should prefer the trial of moderate compression of the radial artery, by means of a graduated compress, or the steel semicircle and screw, occasionally resorted to by Dupuytren, when he wished to check the flow of blood through any particular artery, without stopping the circulation in the limb. I feel confident that this plan would answer, when the ligature of the ulnar artery had not sufficiently commanded the bleeding.

Besides compressing the wounded part of the artery, some surgeons also apply a longitudinal compress over the track of the vessel above the wound, with the view of weakening the flow of blood into it. Whatever good effect it may have in this way, is more than counterbalanced by the difficulty which it must create to the circulation in the arm. If the graduated compress be properly arranged, an effusion of blood cannot possibly happen, and pressure along the course of the artery must, at all events, be unnecessary. After relaxing the tourniquet, if no blood escape from the artery, the surgeon (supposing it to be the brachial artery wounded) should feel the pulse at the wrist, in order to ascertain that the compression employed is not so powerful as entirely to impede the circulation in the fore-arm and hand. The arm is to be kept at rest in a sling, and in forty-eight hours, if no bleeding take place, there will be great reason to expect that the case will do well. In another work, I have given an engraving and description of an instrument, invented by Plenck, for making pressure on the wounded brachial artery, at the bend of the arm, without pressing upon the whole circumference of the limb, and consequently without stopping the circulation. No one, however, would prefer compression when large arteries are injured, except in the kind of cases to which we have just now adverted, or in those in which the wounded vessel can be firmly compressed against a subjacent bone. Sometimes the compresses slip off, or the bandages become slack, and a fatal hæmorrhage may arise; and a still greater risk is that of mortification from the constricted state of the limb. When the method is tried, the tourniquet should always be left loosely round the limb, ready to be tightened in an instant. Sometimes the external wound heals, while the opening in the artery re-

mains unclosed, and a false aneurism is the consequence.

TOURNIQUET.

At the present day, the means for the temporary stoppage of the flow of blood through the arteries in operations, are reducible to two, viz. pressure, and, in a few instances, the preliminary application of a ligature on the trunk of the vessels expected to bleed in a dangerous degree. Pressure is made either with mechanical instruments or the hand. In amputations, M. Dupuytren rarely employed any other means but the hand of an intelligent assistant; and it was only in special cases that he had recourse to the ligature or mechanical pressure. The same rule is adopted by Mr. Liston in University College Hospital; and I sometimes dispense with the tourniquet myself. Two conditions are necessary to render pressure effectual, whether made with an instrument or the hand; the superficial situation of the artery, and its position upon a bone, or some other part sufficiently unyielding to admit of the vessel being pressed against it. (See *Dupuytren, Clin. Chir.* t. iv. p. 377.)

M. Dupuytren confirms what every experienced operator is well aware of, namely, the fact of the flow of blood through the larger arteries admitting of being commanded by means of moderate pressure. But this must be made with precision, and perpendicularly to the surface, which serves as a point of resistance. The inclination of the surfaces of the bones on which the vessels lie, should therefore be recollected. For example, that of the upper surface of the horizontal branch of the os pubis faces upwards and forwards, and that of the first rib upwards and slightly outwards. Consequently, in the groin, the pressure should be directed from above downwards, and from before backwards; and in the hollow, above the clavicle, from above downwards, and from without inwards. If the operation about to be performed is likely to be long, or the artery is large or rather deep, M. Dupuytren recommends the assistant to place the fingers of his unemployed hand over those which compress the vessel, in order to second their action, and hinder them from being fatigued. But, before beginning the operation, the surgeon is always to assure himself of the exactness of the pressure. In some regions of the body, and in thin persons, the diastole and systole of the vessel are perfectly visible, and then the stoppage of them denotes that the pressure is well made. The total interruption of the pulsations, as ascertained by the touch, will leave no doubt on this point. There are some amputations, in which every modification of pressure may be dispensed with, even though arteries of great size are concerned: such are cases, in which the principal artery will be cut only in the final division of the parts, and in which an assistant, who can be relied upon, will let his fingers follow closely the knife, and seize hold of the flap containing the artery, and compress this vessel just before the section of the flap is completed. This method is practicable in amputations at the shoulder, and even in those of the hip. M. Dupuytren knew of only one case in which the preliminary ligature of the artery was absolutely necessary in amputation, viz. that in which the disorganisation of parts, and of the artery in particular, is such, that a definitive ligature on the surface of the stump would in all probability fail. In

this circumstance he sanctions tying the arterial trunk above the point at which the amputation is to be performed. (See *Clin. Chir.* t. iv. p. 382, 385.) I would ask, however, should this measure be preliminary, or ought it not rather to be deferred till the failure of the ligature on the face of the stump has been proved? The performance of two severe operations, instead of one, must never be undertaken without a positive necessity. Most of the preliminary operations on the trunks of arteries, hitherto performed for the prevention of hæmorrhage during amputations, and in the removal of the upper or lower jaw, are now considered to have been unnecessary. In England, we should never amputate in parts known beforehand to be so disorganised, that ligatures would have no chance of securing the vessels on the face of the stump.

When hæmorrhage takes place from a large artery in one of the limbs, where the vessel can be conveniently compressed above the wound, a tourniquet, judiciously applied, never fails to put an immediate stop to the bleeding. Until the invention of this instrument, which did not take place till the latter part of the 17th century, and until it was known that a very moderate degree of well-directed pressure on an artery would stop profuse bleeding, surgery was really a very defective art. No important operation could be undertaken on the extremities, without placing the patient in the most imminent peril; and many wounds were mortal, which, with the aid of these simple expedients, would not have been attended with the least danger.

The first invention of the tourniquet has been claimed by different surgeons, and even different nations. But, whoever was the inventor, it was first presented to the public in a form so exceedingly simple, that it seems extraordinary its invention did not happen sooner. A small pad being placed on the principal artery of a limb, a band was applied over it, so as to encircle the limb twice. Then a stick was introduced between the two circles of the band, which was twisted; thus the pad was made to stop the flow of blood into the lower part of the vessel.

Although in the *Armamentarium Chirurgicum* of Scultetus, there is a plate of a machine invented by this author for compressing the radial artery by means of a screw, J. L. Petit is universally allowed to be the first who brought the tourniquet to perfection, by combining the circular band with a screw, so that the greatest pressure may operate on the principal artery.

The advantages of the modern tourniquet are, that its pressure can be regulated with the utmost exactness; that it operates chiefly on the point where the pad is placed, and where the main artery lies; that it does not require the aid of an assistant to keep it tense; that it completely commands the flow of blood into a limb; that it can be relaxed or tightened in a moment; and that, when there is reason to fear a sudden renewal of hæmorrhage, it can be left slackly round the limb, and, in case of need, be tightened in an instant. Its utility, however, is confined to the limbs; and, as the pressure, necessary to stop the flow of blood through the principal artery, completely prevents the return of blood through the veins, its application cannot be made very long without inducing mortification. It is of use also in putting a sud-

den stop to profuse hæmorrhages for a time, that is, until the surgeon has put in practice some other means, the effect of which is more permanent.

In the article AMPUTATION, many observations will be found on the advantages and disadvantages of tourniquets in that operation. M. Dupuytren sometimes employed, instead of a common tourniquet, what he terms a *compressor*, which makes pressure only on two opposite points of the limb; but, as he acknowledges, it would not be sufficient, if it were necessary, as in a case of extreme debility, to arrest the blood in all the arteries of the limb. (See *Clin. Chir.* t. iv. p. 386.) The compressor is an old instrument, consisting of a segment of a circle of steel, and the pressure of which is regulated by a screw. It has often been tried in England for the cure of popliteal aneurism. It is an instrument which I think ought always to be kept ready in hospitals, where many cases present themselves, especially of secondary hæmorrhage from stumps, the palmar arches, &c., where its application might be of important use. Professor Regnoli, of Pisa, in a case of aneurism, where secondary hæmorrhage took place from the femoral artery, high up the limb, and where, in consequence of disease, another ligature would probably have failed, applied Dupuytren's compressor, and thus made moderate pressure on the bleeding point with complete success. (See AMPUTATION and TOURNIQUET.)

LIGATURE.

The ancients were quite unacquainted with the use of the tourniquet; and though some of their writers have made mention of the ligature, they do not seem to have known how to make proper use of it, nor to have possessed any other certain means of suppressing hæmorrhage from wounds. In modern times, it is easily comprehensible, that when any great operation was undertaken, while surgery was so imperfect, there was more likelihood of the patient's life being shortened than lengthened by what was attempted. Under these circumstances, it is not surprising that the old practitioners should have taken immense pains to invent a great many topical astringents. But now that the ligature is known to be a means which is safer and less painful than former methods, no longer search need be made for specifics against hæmorrhage.

It may, indeed, be set down as a rule in surgery, that whenever large arteries are wounded no styptic application should ever be employed; but immediate recourse had to the ligature, as being, when properly applied, the most simple and safe of all methods.

In order to qualify the reader to judge of the best mode of applying ligatures to arteries, I shall first explain to him their effects on these vessels, as related by Dr. Jones.

This gentleman learned from Dr. J. Thomson, of Edinburgh, that in every instance in which a ligature is applied around an artery, without including the surrounding parts, the internal coat of the vessel is torn through by it; and that this fact had been originally noticed by Desault. Dr. Thomson even demonstrated to Dr. Jones, on a portion of artery taken from the human subject, that the internal and middle coats are divided by the ligature. (*Jones*, p. 126.)

This led Dr. Jones to make some experiments on the arteries of dogs and horses, tending

to the conclusion, that *when several ligatures are applied round an artery*, with sufficient tightness to cut through its internal and middle coats, although the cords be immediately afterwards removed, the vessel will always become impervious at the part which was tied, as far as the first collateral branches, above and below the obstructed part. Dr. Jones thinks it reasonable to expect that the obstruction produced in the arteries of dogs and horses, in the manner he has related, "might be effected by the same treatment in the arteries of the human subject; and, if it should prove successful, it might be employed in some of the most important cases in surgery. The success of the late important improvements, which have been introduced in the operation for aneurism, may perhaps appear to most surgeons to have rendered that operation sufficiently simple and safe; but, if it be possible to produce obstruction in the canal of an artery of the human subject in the above-mentioned manner, may it not be advantageously employed in the cure of aneurism, inasmuch as nothing need be done to prevent the immediate union of the external wound?" Dr. Jones next questions, whether this mode of obstructing the passage of blood through the arteries may not also be advantageously practised in cases of bronchocele? (P. 136.)

Subsequent experimenters have not been equally successful with Dr. Jones in obtaining the obliteration of the cavity of the vessel after this operation. Did this difference depend upon their having tied the vessel only in one place? Mr. Hodgson tried the experiment in two instances upon the carotid arteries of dogs, and in neither of them was the cavity of the vessel obliterated. The same experiment has been repeated by several surgeons upon the arteries of dogs and horses; but in no example, as far as Mr. Hodgson knows, has the complete obliteration of the cavity of the vessel been accomplished. However, as an effusion of lymph is an invariable consequence of the operation, the want of union is owing to the opposite sides of the vessel not being retained in a state of contact, so as to allow of their adhesion. (See *Obs. on the Application of the Ligature to Arteries, &c.*, by B. Travers, vol. iv. *Med. Chir. Trans.*) The presence of the ligature, in the common mode of its application, effects this object; and, for the success of Dr. Jones's experiment, it appeared only necessary that the opposite sides of the wounded vessel should be retained in contact, until their adhesion had been sufficiently accomplished to resist the passage of the blood through the tube. This object might probably be effected by compression; but the inconveniences attending such a degree of pressure as would retain the opposite sides of an artery in contact at the bottom of a recent wound, are too great to permit its employment. It occurred to Mr. Travers, that, if a ligature were applied to an artery, and suffered to remain only a few hours, the adhesion of the wounded surfaces would be sufficiently accomplished to insure the obliteration of the canal; and by the removal of the ligature at this period, the inconveniences attending its stay would be obviated. The danger produced by the continuance of a ligature upon an artery arises from the irritation which, as a foreign body, it produces in its coats. Ulceration has never been observed to commence in less than twenty-four hours after the application of a ligature; whilst it is an

ascertained fact, that lymph is in a favourable state for organisation in less than six hours, in a wound the sides of which are preserved in contact. (*Jones*, chap. 4, exp. 1.) If it be sufficient, therefore, to insure their adhesion, that the wounded coats of an artery be kept in contact by a ligature only three or four hours, ulceration and sloughing may, in a great degree, be obviated by promoting the immediate adhesion of the wound. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained that if a ligature be kept six, two, or even one hour, upon the carotid artery of a horse, and then removed, the adhesion is sufficiently advanced to secure the permanent obliteration of the canal. It appeared probable that the same result would be obtained upon the healthy artery of a human subject. (*Hodgson, On the Dis. of Arteries, &c.* p. 228 et seq.) Mr. A. C. Hutchison, in the year 1800, tied the brachial arteries of two dogs, and removed the ligatures immediately after their application. In both instances, the complete obliteration of the canal of the artery was the consequence of the operation. (See *Practical Obs. in Surgery*, p. 103.) He has also tried this method, as modified by Mr. Travers, in an operation which he performed for a popliteal aneurism in a sailor, in Nov. 1813. A double ligature was passed under the femoral artery; the ligatures were tied with loops, or slip-knots, about a quarter of an inch of the vessel being left undivided between them. All that now remained of the pulsation in the tumor was a slight undulatory motion. Nearly six hours having elapsed from the application of the ligatures, the wound was carefully opened, and the ligatures untied and removed, without the slightest disturbance of the vessel. In less than half a minute afterwards, the artery became distended with blood, and the pulsations in the tumor were as strong as they had been before the operation. Mr. Hutchison then applied two fresh ligatures: hæmorrhage afterwards came on, amputation was performed, and the patient died. (See *Pract. Obs. in Surgery*, p. 102, &c.) Now, as Mr. Hutchison chose to apply other ligatures, on finding that the pulsation returned, the above case only proves that the artery was not obliterated in about six hours; and we are left in the dark respecting the grand question, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesive inflammation, notwithstanding the return of circulation through it. As for the hæmorrhage which occurred, I think it might have been expected, considering the disturbance and irritation which the artery must have sustained in the proceedings absolutely necessary for the application of not less than four ligatures, and the removal of two of them. According to my ideas, only one ligature ought to have been used, and none of the artery detached. We also have no description of the sort of ligatures which were employed,—an essential piece of information in forming a judgment of the merits of the preceding method. The application, removal, and re-application of ligatures are not consistent with the wise principles inculcated by the late Dr. Jones, and have, in more instances than that recorded by my friend Mr. Hutchison, brought on ulceration of the artery and hæmorrhage. The researches of M. Manec lead him to conclude, with all the best practical surgeons of the present time, that the removal of the ligature at an earlier period than that

of its spontaneous detachment is not likely to answer. He observes, that "the continuance of the ligature on the artery for some hours after the division of the internal and middle coats, is not sufficient in man to produce its closure. The plan succeeds but seldom in animals; dogs, for instance, whose blood is more plastic. On one hand, the adhesion of the parietes of the artery together is so feeble for the first five or six hours after the operation; and, on the other, the clot is so small, that the impulse of the blood and the disturbance of extracting the thread will destroy one and displace the other." (See *P. J. Manec, De la Ligature, &c.* p. 30.) If ever the practice, however, should merit revival, I invite the attention of the profession to the simple invention proposed by Mr. John Barker, of Ipswich, for loosening and removing the ligature. (See ANEURISM.)

It appears, then, that the first effects of a ligature upon an artery are, a complete division of its internal and middle coats, the bringing of its wounded surfaces into contact with each other, and an obstruction to the circulation of the blood through its canal. There must be a small quantity of stagnant blood, just within the extremity of the artery; but this does not, in every instance, immediately form a coagulum capable of filling up the canal of the artery. In most cases only a slender coagulum is formed at first, which gradually becomes larger by successive coagulations of the blood; and hence the coagulum is always at first of a tapering form, with its base at the extremity of the artery. But, as Dr. Jones remarks, the formation of this coagulum is not material; for, soon after the ligature has been applied, the end of the artery inflames, and the wounded internal surface of its canal, being kept in close contact by the ligature, adheres, and converts this portion of the artery into an impervious and, at first, slightly conical sac. It is to the effused lymph that the base of the coagulum adheres, when found to be adherent. Lymph is also effused between the coats of the artery, and among the parts surrounding its extremity. In a little time the ligature makes the part on which it is directly applied ulcerate; and, acting as a tent, a small aperture is formed in the layer of lymph effused over the artery. Through this aperture a small quantity of pus is discharged, as long as the ligature remains; and, finally, the ligature itself also escapes, and the little cavity which it has occasioned granulates and fills up, and the external wound heals, leaving the cellular substance a little beyond the end of the artery much thickened and indurated. (*Jones*, pp. 159, 161.)

In short, when an artery is properly tied, the following are the effects.

1. The first action of the ligature is to pucker up, and press towards one another, the parietes of the artery, and, after they touch, if the ligature is further tightened, the internal and middle coats of the vessel are cleanly and regularly cut through; while the external coat, which, by being forcibly constricted by the ligature, has been the direct means of producing this division, resists the action of the ligature, and becomes interposed between the upper and lower margins of the wound in the other coats of the artery. Thus the ligature now only embraces the external coat, the two divided ones being retracted, one towards the heart, the other towards the capillaries. Hence, the cavity of the artery has a conical shape, above and below

the ligature, and the points of these cones, formed by the edges of the division in the internal and middle coats, which are in apposition, hinder the blood from passing further, and striking against the external coat. As M. Manec observes, the whole operation of the ligature must be concentrated on this point; and the margins of the wound, in the middle and internal coats, are only held in contact, inasmuch as the external tunic presses upon them, and inclines them towards the centre of the artery. This pressure, which is sufficient to close the calibre of the vessel, does not interrupt the vital properties of these two coats; but the external coat, on which the ligature exclusively acts, is killed at the constricted point, and a suppurative, or rather an ulcerative, process must occur in this situation, in order to detach the dead circle of this external coat from the living parts, together with the ligature itself. Thus all the artery becomes severed; the internal and middle coats first; the external at a later period. (See *Manec, De la Ligature des Artères*, p. 14.)

2. Another effect is to occasion a determination of blood to the collateral branches.

3. To allow the formation of a coagulum of blood just within the artery, provided a collateral branch be not very near the ligature. It merits particular notice, however, that, though the nearness of a collateral branch always prevents the formation of the coagulum, it cannot always prevent the completion of the adhesive process. In the experiments made on the arteries of horses and dogs by Mr. Travers, the ligature was purposely applied close to large collateral branches, yet the vessels were safely obliterated. (See *Med. Chir. Trans.* vol. vi. pp. 658, 660.)

4. To excite inflammation in the internal and middle coats of the artery, by having cut them through, and, consequently, to give rise to an effusion of lymph, by which the wounded surfaces are united, and the canal is rendered impervious; to produce a simultaneous inflammation on the corresponding external surface of the artery, by which it becomes very much thickened with effused lymph; and, at the same time, from the exposure and inevitable wounding of the surrounding parts, to occasion inflammation in them, and an effusion of lymph, which covers the artery, and forms the surface of the wound.

5. To produce ulceration in the part of the artery around which the ligature is immediately applied, viz. its external coat.

6. To produce indirectly a complete obliteration, not only of the canal of the artery, but even of the artery itself, to the collateral branches on both sides of the part which has been tied.

7. To give rise to an enlargement to the collateral branches. (*Jones*, pp. 163, 164.)

Every part of an artery is organised in a similar manner to the other soft parts, and its coats are susceptible of the same processes of adhesion, ulceration, &c. as the latter parts are. Hence, the precautions taken to secure the adhesion of other parts, should be observed for the same purpose, with regard to an artery. The vessel is put in a state to admit of adhesion by the ligature, which, when properly applied, cuts through its internal and middle coats, keeps their cut surfaces in contact, and affords them an opportunity of uniting by the adhesive inflammation, as other cut surfaces do. The immediate stoppage of the bleeding is merely

the incipient and temporary part of what the ligature has to accomplish: it has also to effect the adhesion of the internal and middle coats of the artery, which, being the thing on which the permanent suppression of hæmorrhage depends, is the most important. The size and form of the ligature, whether completely flat or irregular, have not been, as Dr. Jones remarks, sufficiently attended to; nor is the degree of force employed in tying the artery often considered. Some surgeons, wishing to guard against the ligature slipping off, tie it with very considerable force; while others, apprehensive of cutting through the artery, or of occasioning too early a separation of the ligature, draw it only sufficiently tight just to prevent the escape of blood. A broad flat ligature is not likely to make such a wound in the internal and middle coats of the artery as is most favourable to adhesion, because it is scarcely possible to tie it smoothly round the vessel, which is very likely to be thrown into folds, or puckered by it, and consequently to have an irregular bruised wound made in its middle and internal coats. By covering also a considerable space of the external coat, it may destroy the very vessels which pass on it in their way to the cut surfaces of the inner coats, and thus render them incapable of inflaming. Even supposing the wound to unite, still such a ligature may cover that part of the external coat which is directly over the newly united part, and, consequently, as soon as it has produced ulceration through the external coat, it will cause the same effect on the newly united parts, and of course secondary hæmorrhage. (*Jones*, p. 168.)

When a ligature is of an irregular form, it is apt to cut through the internal and middle coats of an artery more completely at some parts than at others; but these coats ought to be perfectly cut through, in order to produce an effusion of fibrine from the inside of the vessel, which seems to adhere most securely at its cut surfaces.

Also, when the ligature is not applied with sufficient tightness, the inner coats of the artery will not be properly cut through. Dr. Jones thinks that the ligature being sometimes put on so as to deviate from a circle, has a tendency to produce secondary hæmorrhage.

Dr. Jones conceives that ligatures are best when they are round and very firm; and he adds, that, though only a slight force is necessary to cut through the internal and middle coats of an artery, it is better to tie the vessel more tightly than is necessary merely to cut through its inner coats, because the cut surfaces will thus be more certainly kept in contact, the separation of the ligature expedited, and the danger of ulceration spreading to the newly cicatrised part diminished. The external coat will never ulcerate through before the inner ones have adhered. The limb, however, should be kept in a perfectly quiet state.

I am sincerely glad to find that so accurate an observer as Dr. Jones has refuted the idea, that ligatures occasionally slip off the vessels, in consequence of the violent impulse of the blood. In fact, the blood does not continue to be impelled against the extremity of the artery with the same impetuosity with which it circulated through the vessel before it was tied. The blood is immediately determined into the collateral branches, nor is there any pulsation for some way above the ligature. Dr. Jones, more rationally, imputes this

accident either to the clumsiness of the ligature, which prevents its lying compactly and securely round the artery; or to its not having been applied with sufficient tightness; or to its having that very insecure hold of the vessel which the deviation from the circular application must occasion. (P. 173.)

Another circumstance in ligaturing the cut extremities of arteries, adverted to by Dupuytren, may cause the accident:—"The surgeon (says he) should avoid taking hold of only one side of the artery by placing one blade of the forceps into its canal; for it has sometimes happened that, when only a part of the circumference of the artery has thus been included in the noose, hæmorrhage has come on directly the wound has been dressed." (See *Clin. Chir.* t. iv. p. 399.)

Dr. Jones is of opinion, that in cases of aneurism, in which the artery has only been tied with one ligature, and left undivided, and in which secondary hæmorrhage has arisen, this has most probably been owing, either to a diseased state of the artery; to various contrivances for compressing a large portion of the vessel; to having a loose ligature above the one which is tied; or, lastly, to not tying the artery sufficiently tight to cut through the internal and middle coats, so as to fit them for adhesion. The latter fault can hardly fail to produce a gradual ulceration of those coats, and, of course, to bring on hæmorrhage, which returns with greater violence as the ulceration advances. (P. 176.)

These reflections must also obviously explain why Scarpa's practice of using a largish ligature, with the intervention of a piece of cloth between the cord and the vessel, for the express purpose of hindering the inner coats of the vessel from being divided, must be objectionable, because it may be set down as an axiom, in all operations where large arteries are to be tied, that the quantity of extraneous substances in the wound, and particularly of such as are in contact with the artery, should be diminished as much as possible. And, though I may be disposed to go so far with Scarpa as to believe, that the interposition of a piece of cork or wood is worse than that of a cylinder of linen, I cannot accede to the proposition, that the latter is free from objection, because it rather acts as a cushion than as a body likely to bruise. (See *Mem. on the Ligature of Arteries*, p. 44.)

With the differences in the constitutions of man and animals, I know that the results of experiments on the latter can never be looked upon as a positive proof of what would happen from the same experiments performed on the human subject. The stronger or weaker impulse of the heart, the more or less coagulable nature of the blood, the greater or less degree of general and local irritability, the more or less quick tendency to adhesive inflammation and ulceration, are circumstances which must make in different animals the same experiments lead to different results. The question, whether a small round ligature or a larger flat one, with a piece of linen between it and the vessel, be best, must therefore, after all, be decided, not by Dr. Jones's experiments, nor those of Scarpa or Mislei, but by the practice of surgery on the human body; and that the principles defended in this Dictionary are, on the whole, to be preferred, can hardly be questioned by any man who knows how much less frequent secondary hæmorrhage now is in this metropolis than it was formerly when those principles

were neither observed nor comprehended. (See AMPUTATION, ANEURISM, ARTERIES, and LIGATURE.)

We may next inquire, are small round ligatures most advantageous when arteries are ossified? M. Manec states, that, under these circumstances, such a ligature will break the calcareous and cartilaginous deposits into irregular fragments, so that the external coat, instead of making moderate and uniform pressure on the section of the middle and internal tunics, is distended and violently pushed up by the irregular edges of each fragment. At one of these points, the external coat is likely to give way between the second and fourth day. M. Manec further notices the greater difficulty and slowness with which the exudation of a plastic lymph, the exhalation of an unctuous matter, and the formation of a clot, in an artery thus diseased and tied, occur, than in a healthy artery similarly treated. These considerations lead him to join Boyer (*Mal. Chir.* t. ii. p. 139, 155) in deeming small, round, firm ligatures, or even those which are composed of three or four threads, as improper for ossified arteries; he states, that they ought to be rejected, because they too quickly cut through the external coat. In these particular examples, he expresses a preference to arterial compressors (*presse-artères*), or to Scarpa's method, care being taken not to let the pressure, or constriction, be too considerable. In amputations, cases in which ossified arteries are frequently met with, M. Manec admits the unfitness of any arterial compressors, on account of their irritation and interference with the dressing of the stump. In these instances, therefore, he says, that either Scarpa's method, or, what is better, the introduction of a piece of bougie into the ossified artery, as practised by MM. Dupuytren and Roux, is the only resource. (See *P. J. Manec, De la Ligature, &c.* p. 25.) One inference made by him is, that when an artery is ossified or cartilaginous, the formation of a clot is the only thing which can be confided in as a means of closing the vessel. (P. 30.)

Dr. Jones seems to consider that the advantage of the retraction of the *divided* artery within the cellular tissue is compensated, in the case of the *undivided* artery, by the speedy and profuse effusion of lymph which takes place over and round the vessel at the tied part, and even covers the ligature itself. Another cause of secondary hæmorrhage is the including of other parts in the ligature together with the artery, by doing which the division of the inner coats of the vessel may be prevented.

In the valuable publication of Dr. Jones, to which I have so freely adverted, some secondary hæmorrhages are also imputed to the hidden separation, or laceration, of the recently united parts of an artery by premature and extraordinary exertions of the patient. Hence the necessity for keeping a limb, in which a large artery has been tied, perfectly at rest.

I shall conclude these remarks on the ligature with a few practical rules.

1. Always tie a large artery as separately as possible, but still let the ligature be applied to a part of the vessel which is close to its natural connections.

Besides the reasons for this practice already specified, I may observe, that the inclusion of other living textures in the ligature produces immense

pain, and causes a larger part of a wound to remain disunited; the ligature is also apt to become loose as soon as the substance between it and the artery sloughs or ulcerates. Sometimes the ligature, thus applied, forms a circular furrow in the flesh, and remains a tedious time incapable of separation. In particular, the surgeon should take great care not to include in the ligature considerable nerves or veins: "intolerable pain, and, frequently, very serious effects, would immediately follow the constriction of a nervous trunk. Tying large veins does not produce any instantaneous bad symptoms; but it has often led consecutively to phlebitis, and been followed by symptoms which have too often proved fatal." (*Dupuytren, Clin. Chir.* t. iv. p. 399.)

The blood-vessels being organised like other living parts, the healing of a wounded artery can only take place favourably, when that part of the vessel, which is immediately contiguous to the ligature, continues to receive a due supply of blood through its vasa vasorum, which are ramifications of the collateral arteries. Hence the disadvantage of putting a ligature round the middle of a portion of an artery, which has been separated from its surrounding connections; and hence the utility of making the knot as closely as possible to that part of the vessel which lies undisturbed among the surrounding flesh.

Small arteries neither allow, nor require, these minute attentions to the mode of tying them.

2. When a divided artery is large, open-mouthed, and quite visible, it is best to take hold of it, and raise its extremity a little way above the surface of the wound, with a pair of forceps, or Assalini's double tenaculum. When the vessel is smaller, the common tenaculum is the most convenient instrument.

3. While the surgeon holds the vessel in this way, the assistant is to place the noose of the ligature round it, and tie it according to the above directions. In order that the noose may not rise too high, and even above the mouth of the artery, when it is tightened, the ends of the ligature must be drawn as horizontally as possible, which is best done with the thumbs. A knot is next to be made.

4. As ligatures always operate in wounds as extraneous bodies, and one half of each is sufficient for the removal of the noose when detached, the other should be cut off close to the knot and taken away.

As I have explained in the articles AMPUTATION and LIGATURE, trials have been made of the practice of cutting off both ends of the ligature close to the knot, with the view of diminishing as far as possible the quantity of extraneous substances in the wound.

Upon the whole, the plan is not, however, considered to be advantageous, because the portion of the ligature, left in the wound, whatever be the materials of which it is composed, is never absorbed, but gives rise to small abscesses, or even causes a fistulous opening in a stump, of which I lately saw an instance in University College Hospital. In this case, as the two ends of the ligature had been accidentally, and not intentionally, snipped off, the cause of the fistula was, for nearly a fortnight, unsuspected.

5. When a large artery is completely divided, two ligatures,—one to the upper, the other to the lower part of the vessel,—are commonly necessary,

in consequence of the anastomosing branches conveying the blood very readily into the part of the artery most remote from the heart, when the ligature has been applied only to the upper extremity of the bleeding artery.

6. When a large artery is punctured, and compression cannot be judiciously tried, the vessel must be first exposed by an incision, only a small opening being made in its sheath, and then a double ligature introduced under it, with the aid of an eye probe. One ligature is to be tied above, the other below, the bleeding orifice, with due attention to the principles explained in this article and in that on ANEURISM.

7. Ligatures usually come away from the largest artery ever tied in about a fortnight, and from those of moderate size in six or seven days. When they continue attached much beyond the usual period, it is proper to draw them very gently every time the wound is dressed, for the purpose of accelerating their detachment. Great care, however, is requisite in doing this; for, as Dr. Jones remarks, as long as the ligature seems firmly attached, pulling it rather strongly must act, more or less, on the recently cicatrised extremity of the artery, which is not only contiguous to it, but is still united to that portion of the artery (the external coat) which detains the ligature. (Jones, p. 162.)

TORSION.

As even the most considerable arteries, in cases of lacerated wounds, frequently do not bleed, in consequence of the violent extension of these vessels, and the change produced in the disposition of their tunics, the idea of stopping hæmorrhage, by methodically twisting the end of the wounded arteries, led to trials of what is called *torsion*. The practice was first hinted at by Galen, and proposed in modern days by M. Amussat, in 1829, and about the same period also by MM. Velpeau and Thierry. (See Sanson, *Des Hémorrhagies*, p. 157.) After having ascertained, by experiments on animals, that torsion was capable of arresting hæmorrhage from the femoral, brachial, and carotid, and other arteries of magnitude, M. Amussat tried the method on the human subject in amputation, castration, and the removal of the breast. In one case he adopted it after amputation at the shoulder-joint. In none of these instances did any secondary hæmorrhage arise; but union by the first intention was followed only in one of the cases referred to, viz. that of a child. In 1829, M. Lieber, surgeon to the new hospital at Berlin, tried the plan with equal success; and, about the same period, it was had recourse to with success by Dr. Fricke of Hamburg, by MM. Rust and Diefenbach of Berlin, and by M. Schrader of Dresden. On the other hand, in France, the practice of torsion proved unsuccessful after two amputations performed by Professor Delpech. As the patients did not die of secondary hæmorrhage, perhaps their cases have nothing to do with the advantages or disadvantages of torsion. In the hospital of St. Louis at Paris, however, torsion failed in five out of six cases of amputation. Baron Dupuytren, having been requested by the Institute to make a report of the merits of the plan, tried it in the Hôtel-Dieu, and came to the conclusion, that *torsion may be safely applied to arteries of small calibre, but that it is imprudent to trust to it when they are of large size.* (See *Clin. Chir.* t. iv. p.

410.) In a certain number of instances, torsion of the arteries has been followed by extensive inflammation and abscesses in the sheath of the artery.

With regard to its increasing the chance of union by the first intention, inasmuch as no extraneous substance is left in the wound, experience has not proved that it has any advantage over the ligature (Dupuytren, vol. cit. p. 411); and, as M. Manec's researches show, the process of torsion kills a small portion of the artery, and the little slough is, in point of fact, quite as much an extraneous substance as the ligature itself. (See *Traité Théorique et Pratique de la Ligature*, &c.; also Sanson, op. cit. p. 161.) Torsion is practised in two modes; in one, which is termed by the French *torsion libre*, the end of the artery is taken hold of with a pair of forceps, gently drawn out, and twisted round from four to six or eight times according to its size. This is the plan adopted by M. Thierry (*De la Torsion des Artères*, Paris, 1829), and by Dr. Fricke; but as it has been found sometimes to produce inflammation, extending along the coats of the vessel, and even to rupture a collateral branch, the plan recommended by M. Velpeau is mostly preferred in France. This gentleman takes hold of the end of the artery with a pair of forceps, having a groove or not, draws it out of the wound, and separates it from the surrounding tissues; then he takes hold of it near its base with a second pair of forceps, with which he fixes it, while with the first pair of forceps he performs the torsion, three or four times for small arteries, and eight for large ones. (*Sur la Cessation Spontanée des Hémorrhagies*, &c. Paris, 1830.) Some improvements were made in the practice of torsion by M. Amussat. He prefers forceps with longish flat blades, and which admit of being kept firmly shut with a screw. He aims particularly at dividing the inner coats, at the base of the end of the artery, with his finger-nail, or the second pair of forceps, and then pushes them away from the surface of the wound, as it were, into the vessel. The torsion then only affects the external coat. The artery is thus closed by a kind of double valve, or rather barrier; viz. that formed of the internal coats, and another by the twisted external one.

In practising torsion, great care should be taken not to introduce one of the blades of the forceps into the mouth of the artery, for then all the three coats might be torn, and the bleeding not be stopped. (See Dupuytren, *Clin. Chir.* t. iv. p. 405.)

We find, then, that torsion does not consist in merely twisting the end of the artery, but that the two internal coats are also to be separated from, and pushed back from, the external one by the manœuvres adopted. Then the torsion is of the external tunic.

As the twisted end of the artery sloughs, and necessarily excites some degree of suppuration, this fact seems to explain why torsion is not less objectionable than the ligature, as preventing union by the first intention. On the whole, I believe, that M. Dupuytren's report of it, above referred to, is as correct as it is concise. The ligature only interferes with the union by the first intention in the part of a wound where it lies: the rest may still heal in this desirable manner.

VENOUS HÆMORRHAGE.

Though arterial hæmorrhage in operations has received full attention, it must be acknowledged, with M. Dupuytren, that *venous* bleeding has not

attracted due consideration. At the instant of the soft parts being divided, where the course of the blood has been suspended by compression, a profuse quantity of this fluid sometimes gushes from the wound. Inexperienced surgeons, alarmed by the circumstance, stop the operation, and, by deranging the compression already made, rather increase than lessen the bleeding. Here, according to Dupuytren, *the colour of the blood should guide the operator. If dark-coloured, it comes from the limb below the incisions*, and, as it will soon cease, is of no importance. But, in operating on parts abounding in veins, and in which the circulation has not been interrupted, the dark-coloured bleeding will sometimes go on, fill the wound, and hinder the operator's proceedings. This is often illustrated in laryngotomy and tracheotomy. In other instances, the blood flows out profusely from the large veins, which are divided, the patient turns pale, and seems as if he would perish on the operating table. Dupuytren observes, that the continuance of such hæmorrhage depends more upon the patient suspending respiration than on the size of the veins, and the blood, not being then able to pass through the lungs, makes its escape from the veins divided in the operation. Here it is inexpedient to apply ligatures, because if one set of veins were tied, another set would begin to bleed. But directly the patient has filled his lungs two or three times completely with air, by making full inspiration, the hæmorrhage ceases. These precepts were never forgotten by Dupuytren, whenever he divided considerable veins, either in the trunk, face, neck, or upper part of the limbs. (See *Leçons Orales de Clinique Chir.* t. iv. p. 392.) It would appear, from the researches of M. Poiseuille, that the interruption of respiration has influence only on the portion of the venous system above the diaphragm. (See *Journ. Univ. Hebdom. de Médecine*, t. i. p. 289, et t. ii. p. 97, 8vo. Paris, 1830.) However this may be, the practical observations of M. Dupuytren are highly important with reference to venous hæmorrhage in the extraction of fibrous tumors from the nose or antrum, tracheotomy, and all other operations in the anterior region of the neck, a region so abundantly provided with veins of all sizes. The long and deep inspirations, however, recommended for the suppression of venous bleedings, are suspected by M. Sanson to have had, in some instances, a share in promoting the entrance of air into the veins, particularly when one of those in the upper part of the body has been wounded, and when, in consequence of its parietes being indurated, it gapes, as was once exemplified to M. Delpech in the axillary vein. (*Clin. Chir. de Montpellier.*) The passage of air into the wounded veins, observed by Beauchène, Dupuytren, Graefe, Mott, and Clemot, usually destroys the patient almost instantly, unless care be taken to place a finger over the wound in the vein, as was done by M. Clemot. (See *Sanson, Des Hémorrhagies Traumatiques*, p. 91.)

The hæmorrhage from the bites of leeches sometimes proves exceedingly obstinate, and instances of death from this cause have occasionally happened, particularly in children. When common methods fail, the plan has been recently tried of passing a fine sewing needle through the skin on one side of the wound, and then another through the skin on the opposite side, and next twisting some thread round the needles, so as to draw them together and close the bite. The experiment fully answered.

(See *Lond. Med. Repository*, Jan. 1819, p. 23—26.) Simply transfixing the leech bite with a single small sewing needle, and passing a ligature around it answers equally well.

[ACUPRESSURE.]

[A novel method of arresting hæmorrhage has been lately introduced by a high authority in obstetric medicine, Dr. J. Y. Simpson, of Edinburgh, to whom the profession and the public are indebted for the selection of chloroform as an anæsthetic in preference to ether, and for many other original and important improvements in medical science. Dr. Simpson gives to this new method the term of "Acupressure," which he recommends to surgeons as a substitute for the ligature, the ordinary means now universally adopted by the profession for securing bleeding vessels. The needles, or rather pins, used for this purpose are straight, and of various lengths and thicknesses, guarded by a knob at one end and pointed at the other, resembling those employed in the operation for hare-lip. The mode of using the pins is described by Dr. Simpson in the *Edinburgh Med. Journal* for Jan. 1860, p. 647, from which I subjoin the following extracts.]

"The whole process consists in passing the needle *twice* through the substance of the wound, so as to compress together and close, by the middle portion of the needle, the tube of the bleeding artery a line or two, or more, on the cardiac side of the bleeding point. In acting upon this mode, the surgeon may place the tip of the fore-finger of his left hand upon the bleeding mouth of the artery which he intends to compress and close; holding the needle in his right hand, he passes it through the *cutaneous* surface of the flap, and pushes it inwards until its point projects out to the extent of a few lines on the raw surface of the wound, a little to the right of, and anterior to, his finger-tip; he then, by the actions of his right hand upon the head of the needle, turns and directs the needle so that it makes a bridge, as it were, *across* the site of the tube of the bleeding artery, immediately in front of the point of the finger with which he is shutting up its orifice. He next, either with this same fore-finger of the left hand, or with the side of the end of the needle itself, compresses the locality of the bleeding arterial orifice and tube, and then pushes on the needle with his right hand, so as to make it *re-enter* the surface of the wound, a little to the left side of the artery; and, lastly, by pressing the needle further on in this direction, its point re-emerges through the *cutaneous* surface of the flap, and the site of the tube of the bleeding artery is in this way left pinned down in a compressed state by the arc or bridge of steel that is passed over it. The needle thus passes first from and through the skin of the flap *inwards* to the raw surface of the wound, and, after bridging over the site of the artery, it passes, secondly, from the raw surface of the wound *outwards* again, to and through the skin. Sometimes the needle will be best passed by the aid of the eye alone, and without guiding its course by the finger-tip applied to the bleeding orifice. To compress a bleeding artery against a bone is somewhat more complicated, but not much so. In accomplishing it, we have to introduce, from the cutaneous surface, a long needle through the flap of the wound obliquely to near the site of the artery, and then compressing, with the fingers of the

other hand or with the end of the needle, the part containing the artery against the bone, we make the needle, after passing over this compressed part, and after testing whether it has closed the vessel or not, enter into the tissues beyond, and, if necessary, even emerge from the cutaneous surface on the other side, at an angle somewhat oblique to that at which it entered; thus taking advantage of the resiliency and resistance of the soft textures to make them push the needle with the necessary degree of compression against the artery and bone. Arteries in particular parts require special adjustments and modifications to compress them against the neighbouring bone, which only experience can point out.

"It has been hitherto a difficult problem to obstruct the vessels of the ovarian ligament in ovariotomy, without leaving a foreign body, whether clamp or ligature, upon the stalk of the tumor, to ulcerate and slough through it. If the stalk be transfixed and pinned in its whole breadth to the interior of the relaxed abdominal walls, by one or more acupressure needles passed through these abdominal walls from without, this difficulty may possibly be overcome."

Dr. Simpson thus sums up the various important advantages which he conceives acupressure to present, as compared with the ligature:—"1st. It will be found more easy, simple, and expeditious in its application than the ligature. 2nd. The needles, in acupressure, can scarcely be considered as foreign bodies in the wound, and may always be entirely removed in two or three days, or as soon as the artery is considered closed; whilst the ligatures are true foreign bodies, and cannot be removed till they have ulcerated through the tied vessels. 3rd. The ligature inevitably produces ulceration, suppuration, and gangrene, at each arterial point at which it is applied; whilst the closure of arterial tubes by acupressure is not attended by any such severe consequences. 4th. The chances, therefore, of the union of wounds by the first intention should be greater under the arrestment of surgical hæmorrhage by acupressure than by the ligature. 5th. Pyæmia and surgical fever seem not unfrequently to be excited by the unhealthy suppuration, &c. in wounds, which are liable to be set up by the presence and irritation of the ligature. 6th. These dangerous and fatal complications are less likely to be excited by the employment of acupressure, seeing the presence of a metallic needle has not the tendency to create local suppurations and sloughs in the wound, such as occur at the seats of arterial ligatures. And 7th. Hence, under the use of acupressure we are entitled to expect both,—*first*, that surgical wounds will heal more kindly and close more speedily; and, *secondly*, that surgical operations and injuries will be less frequently attended than at present by surgical fever and pyæmia."

Dr. Greig, surgeon to the hospital at Dundee, tried acupressure in two cases of amputation of the fore-arm, and in a case of extirpation of the breast, and speaks in the most favourable terms of the facility of arresting hæmorrhage by needles. In a letter to Dr. Simpson, he expresses his intention of employing them in preference to ligatures in all cases under his care. "It is a great comfort," he says, "to both patient and surgeon, that by acupressure the artery is closed in about forty-eight hours (a large artery may, of course, require a

longer time), and all cause of irritation at once removed. In my first case I allowed the needles to remain in for three days; but in future I will consider two days long enough, and, for all I know, perhaps it is longer than is required.

"I have now the greatest faith in acupressure. I intend employing it in all kinds of cases that may come under my care, and I will have no fear whatever to use it in my first thigh amputation.

"In giving directions for securing the vessel, you advise the surgeon to place the fore-finger over its bleeding mouth, &c. Now you will find it much better, when you have a flap, to keep the finger of the left hand on the skin side, and use the thumb. You feel the vessel beating between the thumb and fore-finger, and you can introduce the needle in the dark." (*Medical Times and Gazette* for Feb. 11, 1860, p. 137.)

Acupressure has likewise been practised to arrest hæmorrhage by Mr. Adams, of London; Mr. Edwards, of Dundee; Mr. Page, of Carlisle; Mr. Bickersteth, of Liverpool; Drs. John and James Struthers, of Leith; and Mr. Dickenson Crompton, of Birmingham; who appear to approve of the proceeding. It has not, however, been generally adopted; nor is it, in my opinion, likely to supersede the use of the ligature, notwithstanding the powerful advocacy of its claims by its talented proposer.

Above all things the surgeon desires after his operations to feel assured that his patient is left secure from hæmorrhage, as regards the principal arteries of a limb. He knows that in his absence a few seconds of bleeding from a main artery will terminate the existence of his patient. No minor advantage in the healing of the wound can compensate for the risk and for the painful anxiety attending the idea that he may have left his patient liable to such a catastrophe. The most secure method, the one least liable to accidental disturbance, will always be preferred by the generality of surgeons. The ligature properly applied fulfils this all-important requirement. It remains to be proved whether acupressure can be equally depended upon, and whether stumps and wounds, in which acupressure has been resorted to in preference to ligatures, will heal more kindly by the first intention, and will be less likely to be followed by sloughing, by abscess, or pyæmia. It should be remembered that as many as a dozen ligatures may be required in some operations, and that acupressure needles to this amount must seriously interfere with the adjustment of the wound; and it is to be feared, also, that a stump thus circumstanced cannot so readily be supported without disturbing the needles, or interfering with the relative pressure exerted by each on the artery it is intended to constrict. Another advantage possessed by the ligature is, that the artery can be selected from the surrounding textures, and alone constricted; while in acupressure the vein, the nerve, and other structures, are equally subjected to pressure with the artery itself. It is but fair to state, however, that this pressure has not hitherto been found injurious, and that no patient has as yet suffered from a recurrence of bleeding where acupressure has been resorted to, although four thigh amputations are included amongst the cases thus treated,—one by Dr. James Struthers, of Leith, two by Mr. Dickenson Crompton, of Birmingham, and one just below the trochanters, by Dr. Handyside, of Edinburgh.

(See *Edin. Med. Journ.* for Dec. 1860, pp. 504, 567; also for Feb. 1861, p. 692.)]

[HÆMORRHAGIC DIATHESIS. *Hæmorrhagic crasis* (auc. var.); *Hæmorrhopilis* (*Rokitansky*). A watery condition of the blood, coupled with a preternaturally delicate and vulnerable structure of the coats of the vessels.

This disease is by no means of uncommon occurrence in this country, and is met with in America, but is believed to be most frequent in Germany.

It is for the most part hereditary, affecting the males in families, although occasionally the females, and is very often transmitted for many generations to the males from the maternal grandfather through the mothers, although in some families the females have been known to die in after life during childbirth or from uterine hæmorrhage. It most commonly manifests itself at a very early period; but there is no certainty as to this, since it sometimes occurs for the first time in adult age. The liability to it declines as age advances, individuals of this diathesis having lived to be old, and died of other diseases. Men marrying healthy wives are said not to transmit the tendency to their progeny. Although hereditary in this remarkable manner, it is occasionally induced, even in this country, in previously healthy subjects, by anti-hygienic influ-

ences, as deficiency of food, pure air, light, and exercise.

Dr. John Hay asserts that "the children of bleeders are never subject to this disposition; but their grandsons by their daughters are." The circumstances connected with a case recorded in Mr. Wardrop's work, by Mr. Ward, of Ewell, are as follows: "His mother has a numerous offspring, and a brother who is twenty-two years old is afflicted in a similar way, and is also an almost constant sufferer with rheumatic gout. He had five uncles and two aunts; all his uncles had the same hæmorrhagic tendency. Three died from slight wounds, as division of the frænum linguæ, and the other had the same disease, but died from some other cause. The aunts had not that tendency in their persons; the one had three boys, two of whom were thus afflicted; the other had two boys and two girls; both boys were afflicted in the same way." Mr. Lane, from an investigation of the cases before him, at the time he wrote, came to the conclusion "that males only are subject to this peculiarity of constitution; that the father of a bleeder is always free from the disease; that the son of a bleeder is never affected by it; that the bleeder inherits this tendency invariably from his maternal grandfather." (*On the Hæmorrhagic Diathesis*, by *Samuel Lane*. *The Lancet*, 1840, vol. i. p. 185.) The later experience of the Germans seems to have shown that this is not an absolute law, although a very general rule.

The blood in this disease is essentially hydræmic, deficient in fibrine, and in extreme cases non-coagulable. The fibrine occurs in diminished proportion absolutely, and also in relation to the red corpuscles; differing in the latter particular from the blood of chlorosis. When coagulation takes place, the clot, remarkably destitute of firmness, is porous, being easily permeated by fluid, and consequently useless as a hæmostatic. Some observers have found the red corpuscles altered in structure, angular, or otherwise misshapen, jagged, and serrated; but in the early stages the blood is of the ordinary colour. Most of the structures, including the capillary vessels, and especially the arteries, are remarkably fine. The diminution of fibrine is accompanied with diminished viscosity. There is thus, failure, both in the coagulability of the blood and in the contractility of the vessels, the latter becoming almost passive and easily dilatable tubes, with a degree of fluidity of their contents favourable to hyperæmia and hæmorrhage.

The disease most frequently proves fatal by capillary hæmorrhage. The hæmorrhage is sometimes the result of a solution of continuity, and sometimes spontaneous. It is most severe from lacerated wounds. It may be periodical, recurring at regular or irregular periods, and has been known to return annually. Death may result from the slightest wound or surgical operation, and has happened very frequently from the abstraction of a tooth. Cases are also recorded in which the operations of bleeding, cupping, the introduction of a seton needle, the division of the frænum linguæ, also the accidental biting of the tongue, or a slight wound of a finger, have proved fatal. A small pebble fell on the nail of a finger of a boy under two years old, and blood issued from the end of the finger till he bled to death. (*Dr. J. C. Otto*, lib. cit. passim.) Frequently all the males of a family die of it. Sanson, in his Thesis

for 1836, mentions the case of a man who died of urethral hæmorrhage, and six of his children from bleeding from casual wounds. In one family, Dr. Otto states, "So assured are its members of the terrible consequences of the slightest wound, that they will not suffer themselves to be bled on any consideration." The blood proceeds from the capillaries or the minutest ramifications of the arteries, no branch of any importance being involved.

This disease frequently exists without manifesting itself by any symptoms; and it is not until some accident occurs, or some operation has been performed, that the condition of the blood and blood-vessels becomes known. At other times a certain delicacy of constitution exists, by which, with the hereditary tendency, it may be predicated. In the more severe and fatal cases, apart from the accidental occurrence of hæmorrhage, there is a tendency to dropsical effusions. Ecchymoses also take place on the slightest pressure, or even spontaneously, and disappear slowly, leaving a yellow tint. Bullæ frequently occur filled with blood. There is a liability also to attacks of pain and swelling of the wrists, ankles, and knee-joints, attended with fever, which have been attributed to rheumatism, but can have no real analogy to that disease, in which the blood is essentially hyperinotic. The subjects of this disease are also more especially liable to epistaxis, hæmatemesis, hæmoptysis from the slightest cough, melæna, hæmaturia, and other hæmorrhages. A febrile paroxysm usually attends when the hæmorrhage sets in; but the symptoms of loss of blood rapidly supervene. The blood, at first of the usual colour and feebly coagulable, becomes gradually paler, and ultimately nearly colourless and incoagulable, the fibrine becoming exhausted, and the red corpuscles, which at first existed in something approaching their normal proportions, being also greatly diminished. There is loss of appetite; sometimes, but not always, thirst; the urine becomes gradually more and more limpid, and smaller in quantity, until it ultimately ceases to be secreted; the lips become dry; the breathing slow, with frequent sighing, and the action of the heart irregular, intermittent, and indistinct, and ultimately it ceases.

The theory has been advanced that this disease is the result of excessive hæmatosis, in relation to the strength and calibre of the vessels; the febrile and reactionary symptoms recurring periodically being the result of a certain degree of relative plethora; since even wounds are not followed by excessive hæmorrhage during the intervals. The hæmorrhage also is of rare occurrence in men affected with hæmorrhoids and in women during the menstrual period of life, and, as will be seen under the head of "treatment," it is often prevented by circumstances which diminish the quantity of the blood in the vessels, as purging and other depleting measures.

Schreyer states of a boy five years and another fifteen months old: "Both present, at variable intervals, on their legs and thighs, a number of blue spots which swell to the size of a pigeon's egg and then assume a yellowish green shade; they do not bleed, unless when opened artificially, but the hæmorrhage continues until the patient falls into a swoon, and his body becomes pale as death. The blood is at first red, and subsequently resembles water in which raw meat has been

steeped; and at this period of the hæmorrhage the blue colour of the spots disappears. The further progress of the bleeding is arrested by the pressure of the finger on the orifice, which it is generally necessary to continue for twenty-four hours. The orifice is never closed by a well-formed coagulum. The children slowly recover, and continue to all appearance healthy until the next renewal of the hæmorrhage." (*Andral, Path. Anatomy, by Townsend and West, vol. i. p. 418.*)

The causes of this disease are involved in obscurity. Mr. Millar remarks that it bears an analogy, in some respects, to tuberculosis (scrofula), and in others to scorbutus. Virchow, on the principle that every dyscrasia is dependent upon a permanent supply of noxious ingredients from certain sources (*Cellular Pathology, transl. by Dr. Chance, p. 132*), points to the spleen or liver as being obviously associated with its production in many instances; but he admits that from our want of knowledge of the influence exerted by these organs over the special composition of the blood, it is impossible to determine how they produce such an effect. Leukæmia, in its advance towards its usually fatal termination, develops this hæmorrhagic state of the blood. In this disease, the spleen and lymphatic glands are the organs most frequently affected. (See LEUKÆMIA.)

On the post-mortem examination of a boy aged between three and four years, who died from biting his tongue, Mr. Wilson records that "the coats of the vessels of the arterial system were not more than half their usual thickness," and he attributed the hæmorrhagic tendency to a deficiency of the contractile power in the arteries. (*Lane, lib. cit. p. 187.*)

In the last edition of this Dictionary Mr. Cooper remarks: Sometimes this extraordinary disposition to hæmorrhage is owing to an accidental cause little suspected. Thus, in an example which happened in the practice of M. Dupuytren, a tumor was found in the right auricle, completely blocking up and greatly dilating the superior vena cava, and extending into the jugular vein up the lower third of the neck: it also filled up the right subclavian vein. The patient, a young woman, lost fatal quantities of blood from the wound of the skin in venesection, and from the socket of a tooth. The actual cautery and all other means were tried in vain. (See *Sanson, Des Hémorrhagies Traumatiques, p. 21.*) A mechanical obstacle to the circulation, situated either in the heart or blood-vessels, is noticed by Dr. Carswell, as one of the causes of hæmorrhage; and, besides solutions of continuity, he likewise enumerates as causes a modification of the functions of the capillaries, as evinced in vicarious hæmorrhage, and that from erectile tissue. Nor does he omit a diseased state of the blood, as exemplified in scurvy, and some forms of purpura, and typhus fever. (See *Carswell's Illustrations of the Elementary Forms of Disease, fasc. 6.*)

[In illustration of the impropriety of the performance of surgical operations on the subjects of this disease, Dr. Millar has the following quotation:—"In a patient of a hæmorrhagic tendency, affected with white swelling of the knee-joint, a puncture of the tumor with a lancet was followed by the most alarming bleeding; yet a surgeon was found bold enough to propose amputation, which accordingly was performed in opposition to the opinion of a more cautious practitioner. The principal

bleeding vessels were secured as usual, yet the patient bled to death, the blood continuously oozing from the stump in spite of all applications. (*Lancet*, No. 138, p. 99.)

Treatment.—For the purpose of improving the condition of the blood, and correcting the hæmorrhagic tendency, a tonic and invigorating course is indicated, and in particular, a full nutritious diet and free exposure to the open air and light, with the avoidance of all exhausting or debilitating habits. Iron, cod-liver oil, and bitter tonics have also to be employed, the first two being especially useful by increasing the amount of red corpuscles and diminishing the hydræmic condition of the blood. Whether the inhalation of an increased amount of oxygen, either by means of an apparatus for the purpose or the compressed air-bath, would produce a permanent increase of the fibrine, there are no experiments to determine. Saline purgatives have been found particularly useful. In one case, hæmorrhage appeared to be averted for a long period by a full dose of sulphate of magnesia taken as a purgative once a week. Citric acid has also been proposed as a prophylactic, owing to the resemblance which the disease bears to scurvy. But no general plan of treatment of this kind can avail much when the hæmorrhage sets in. Persons of this constitution should avoid occupations in which they are liable to wound or otherwise injure themselves.

In the treatment of the hæmorrhage much depends on energy, promptitude, and the judicious selection of remedies. Mr. Millar points out the desirableness of bearing in mind, that when the bleeding commences the blood is coagulable, which ceases to be the case as it continues to flow. Where the vessel could be reached all the usual methods of compression and the most powerful styptics, as the acid nitrate of mercury, the potential and the actual cautery, have been resorted to, sometimes successfully; but it has too frequently happened, even when the bleeding has been arrested, that it has broken out again, or that upon a subsequent attack the case has proved fatal. These remedies are treated of in full under another head (see HÆMORRHAGE); we therefore limit ourselves in this place to a statement of views entertained on the arrest of hæmorrhage in the hæmorrhagic diathesis.

Mr. Wardrop justly remarks, that substances which dispose the blood to coagulate have more effect in restraining the bleeding for a time than those which excite the arteries to contract. In the earliest stage the invigorating general treatment, already described, is indicated, to maintain or increase the amount of fibrine in the circulating blood. As the blood flows, at first more of the globules than of the fibrine are wasted and the proportion of the latter becomes relatively increased, a circumstance favourable to coagulation. Stimulants should not be resorted to in this stage, since they are calculated to rouse the circulation, and prevent that approach to syncope which frequently occurs and sometimes leads to coagulation. One patient took a bottle of port-wine daily, but continued to sink till the system of treatment was abandoned. (*Lancet*, No. 974, p. 149.) Mr. Millar suggests an irritant applied to some distant part and rapidly exciting a superficial inflammation, as feasible and safe, for the purpose of increasing the quantity of fibrine in the general

mass of blood, and also acting as a derivative. And this gentleman remarks, that it is not rapid coagulation, usually affording a loose and porous clot, which is required, but just that solid and efficient clot which results from the slow coagulation of blood in inflammations. Dry cupping is also suggested as a derivative. "For the purpose of calming the general circulation and depressing the influence of the nervous system, thereby favouring a coagulation of the blood in the vessels," acetate of lead and opium may be given in doses of three to five grains of the former to half a grain of the latter, every four or six hours, according to the urgency of the symptoms. Of the astringent class of medicines, twenty grains of sulphate of alumina, every two or three hours, is amongst the best. A full dose of oil of turpentine has been successful in some hands. Nauseating doses of ipecacuanha or tartarised antimony are also recommended to moderate the general circulation and promote the coagulation of the blood in the capillaries, and to remove the febrile condition which attends the early stage of the hæmorrhage; but these should never be carried to emesis. Purgatives, and particularly the sulphate of soda, administered several days in succession, have been found remarkably useful in arresting the hæmorrhage, by Dr. Otto, Dr. Hay, and others. This has been attributed to their effect in diminishing the serous part of the blood. Elaterium, for the same purpose, is suggested by Mr. Millar, with the remark that its exhibition is practicable, administering support at the same time. Andral considered sulphate of soda the most efficient substance to retard the commencement of coagulation, and render the clot firm; and Mr. Millar adds that it is useful in obviating any bad effects that might result from a previous exhibition of lead, but the two remedies cannot be administered together. Upon the whole, Mr. Millar seems to regard the *Pil. Plumb. Opiat.* as the most powerful remedy, acting favourably on the blood, calming the circulation, subduing the nervous influence, and "correcting the degeneracy of the capillaries themselves." Wachsmuth recommends *secale cornutum* in doses of five grains every half-hour. The Germans, who regard the spontaneous bleedings as critical, lay it down as a principle that they should not be arrested too quickly lest a vicarious hæmorrhage occur in some vital organ.

Amongst the topical applications, Mr. Millar condemns the use of the *cautery*, actual or potential, in very decided terms. He believes that in the hæmorrhagic diathesis they have no virtue as hæmostatics, and that the former, especially, inflicts almost irretrievable injury. "The vessels are unable to pucker and contract; the eschar is comparatively soft, and will not adhere; if it does adhere, it is imperfectly, and for a short period; the parts have no plastic power necessary for permanent occlusion; and the result is, that the cauterisation either does not arrest the bleeding at all, or it does so only in part, besides mystifying and obscuring the source of the hæmorrhage; or if the cessation be satisfactory at first, the flow returns in a few hours with redoubled vigour; the bleeding surface is increased, the part is being inflamed, and more blood is sent thither, and perhaps, worst of all, it is fast becoming wholly intolerant of pressure." Mr. Millar quotes numerous cases which practically illustrate the correctness of these views, showing that in a great major-

rity of the cases in which it has been employed death has resulted. To distinguish between *ordinary* hæmorrhage of local origin, and that proceeding from a *constitutional vice*, is thus of the greatest importance, "seeing that in the one the cautery may be demanded, and its use prove profitable; while in the other it will not only fail, but injure."

Deligation of the principal arterial trunk, which has occasionally been resorted to, is equally condemned by the eminent surgeon from whose paper we have so largely quoted. In Mr. Blagden's case of hæmorrhage after extraction of a tooth, quoted at large in former editions of this Dictionary, after the failure of a variety of remedies, including the cautery, Sir B. Brodie tied the carotid; but the case proved fatal. After tying a principal vessel, the flow of blood is quickly resumed on the distal side (see HÆMORRHAGE), and the capillary hæmorrhage can be but little, if at all, affected. Even should the original hæmorrhage be arrested, the patient's life will be compromised by bleeding from the recent wound. In a case of Mr. Wardrop's, in which the hæmorrhage was induced by the insertion of a seton, this gentleman secured no less than nine vessels; blood continued to ooze from innumerable small orifices over the whole surface of the wound, which every mode of treatment usually resorted to failed to arrest, and the patient died. (*On Bleeding*, p. 14.) M. Roux tied the radial and ulnar on account of bleeding from the palm; his patient died in the course of the evening; the blood oozed not only from the palm of the hand, but also from the two incisions of the fore-arm." For analogous reasons, general inclusion of the bleeding surface by ligature is equally inappropriate.

Styptics, by their local and astringent effects upon the capillaries, are useful in this, as in ordinary hæmorrhage; but the remedy most to be relied on is *pressure*. Creosote, perchloride of iron, or nitrate of silver, by forming a coagulum, may act powerfully for a short time as hæmostatica, and fulfil the important indication of obtaining a dry bed for a compress of lint or cotton; but their continued use being inconsistent with pressure, and far less important when this can be applied, they must be abandoned if they do not quickly take effect. Mr. Millar gives conclusive evidence, from numerous cases, of its beneficial results, and states his belief that, in every successful case, pressure, early and judiciously employed, has been found one of the most important agents of the cure. A lacerated wound has been known to cease to bleed by converting it into an incised wound.

All other remedies failing, the operation of *transfusion* has been resorted to. Mr. Lane had a successful case, the progress of which the writer of this article watched. The patient was a lad eleven years old, who had exhibited the hæmorrhagic tendency on former occasions. He had bled for six days from a wound made in the operation for strabismus, and was reduced to the most extreme state of spanæmia, threatening immediate dissolution, and as a last resource, when all hope had vanished, was saved by transfusion from the vein of a "stout healthy young woman." "The wound at the bend of the arm healed in about ten days, and the boy, after being wheeled out in a hand-carriage in the open air, soon recovered his appetite and strength, and in about three weeks

went into the country, whence he returned in a few days perfectly well." (*Lancet*, vol. i. 1840, p. 185.) It is worthy of record that this lad died of consumption a few years afterwards.

Mr. Millar remarks on this operation:—"There is a risk of bleeding continuing to a dangerous extent from the wound made to reach the vein; but experience is not so very unfavourable on this point." "Wounds of the larger blood-vessels, such as that in venesection, are usually found to heal as readily in hæmorrhagic individuals as in any other set of patients. This, however, is not always the case." (*Med. Chir. Rev.* vol. xxix. p. 228.) "Hæmorrhagic patients have perished by the venesection wound. Such risks will justly deter us from having recourse to transfusion until other means have been tried and failed. But when *in extremis*, we ought surely to afford the patient the chance, and that no improbable one, to be derived from this *dernier ressort*, the more especially as we have at least one good fact in its favour afforded by Mr. Lane." (*On the Treatment of the Hæmorrhagic Diathesis*, by James Millar, Esq., F.R.S.E. &c. London and Edin. Monthly Journal, 1842, p. 567. This paper contains references to numerous cases and to the literature of the subject generally.)]

HÆMORRHOIDS (from αἷμα, blood, and ῥέω, to flow). See PILES.

HÆMOSTATICS. Substances which arrest hæmorrhage. Of these the coagulum of blood is the most important. The greater the proportion of fibrine in the blood, and the more dense the clot, the greater its power as a hæmostatic. (See HÆMORRHAGE, HÆMORRHAGIC DIATHESIS.)

HARE-LIP. (*Labium Leporinum*, Lat.; *Bec de Lièvre*, Fr.; *Hasenscharte*, *Lippenspalt*, Ger.) A fissure or perpendicular division of one or both lips. The term has arisen from the fancied resemblance of the part to the upper lip of a hare. Occasionally the fissure is more or less oblique: it may be directly below the septum of the nose, or correspond to one of the nostrils. The two portions of the lip are generally movable, and not adherent to the alveolar process; in some cases they are closely attached to it.

Children are frequently born with this kind of malformation, which is called a *natural* hare-lip, while that which is produced by a wound is named

accidental. Sometimes the portions of the lip, which ought to be united, have a considerable interspace between them, while in other instances they are not much apart. The cleft is occasionally *double*, a little lobe, or small portion of the lip, being situated between the two fissures; this is termed a *double hare-lip*.

The fissure mostly affects only the lip itself, and usually the upper one. In many cases, however, it extends along the bones and soft parts forming the palate, even as far as the uvula; and sometimes those bones are entirely wanting. In a few instances, the jaw not only is imperfectly ossified in front, so that a cleft presents itself there, but one side of it projects forward, and is at the same time inclined too much outward, drawing with it the corresponding part of the palate, and the septum nasi, so that a very unsightly distortion of the nostril and nose is produced. Such cases are denominated *complicated hare-lips*.

[These deformities are often hereditary. Several children of the same parents have been so born. Mr. C. Forster records a very interesting case in which of nine children of a father who had hare-lip, two had hare-lip, and one defective palate; others had imperforate rectum. After the birth of the ninth child the operation for hare-lip was performed on the father, and there have been two healthy children since. (*Surgical Diseases of Children*, p. 30.) In common with many other deformities, hare-lip is the result of some arrest or irregularity of foetal development. Simple hare-lip is merely non-union of the median labial fissure. This may be complicated by arrested development of one or more portions of the superior maxillary bone. The incisive portions of the bone, including the two incisor teeth on each side, have separate centres of development. In some animals each constitutes a separate inter-maxillary bone; and in some cases of hare-lip it remains more or less perfectly detached—any fissure that may exist corresponding to the line of union between the maxillary and inter-maxillary bones, or rather between the incisive and the palatal and facial portions of the maxillary bone. There is, very rarely however, a central fissure with two lateral fissures superadded. Central fissure, resulting from non-union of the incisive and palatal portions of the two bones, accompanied by non-union of the soft parts, may be continued backwards through both hard and soft palate, and often so that there is free communication between the nasal and oral cavities. Fissure of the hard palate on one side only of the vomer is rare. In many of these complicated cases the soft palate is deeply fissured.

All these clefts or fissures are due to arrest of development prior to the end of the third month of foetal existence. Wagner (*Verhandlungen der Gesellschaft für Geburtshilfe in Berlin*) has seen two cases where union of the labial cleft took place within the uterine cavity. Dr. P. Frank, who saw one of these cases, has informed me that it was on the left side of the upper lip. Union had taken place with a distinct red cicatrix, and that deep indentation of the free margin which it is our object to avoid in operative proceedings.

Fissure of the lower lip, in the median line, is sometimes seen, and may be complicated by more or less fissure in the lower maxillary bone, but it is very rare.]

A hare-lip, in its least degree, occasions consi-

derable deformity; and when more marked, it frequently hinders infants from sucking, and makes it indispensable to nourish them by other means. When the lower lip alone is affected, which is rare as a malformation, the child can neither retain its saliva, nor learn to speak, except with the greatest impediment. The constant escape of the saliva, besides being an annoyance, is found to be detrimental to the health; for its loss impairs the digestive functions, the patient becomes emaciated, and even death would sometimes ensue, if the incessant discharge of so necessary a fluid in the animal economy were not prevented. Thus, a lady, who was in this state, consulted Tronchin, who immediately saw the cause of her indisposition, and recommended the fissure in the lip to be united: the operation was done, and the dyspeptic symptoms then ceased. And when the fissure pervades the palate, the patient not only articulates very imperfectly, but cannot masticate nor swallow, except with great difficulty, on account of the food readily getting up into the nose.

[It is believed that Dieffenbach's observation is confirmed by others, to the effect that more infants are born with double than with single hare-lip; and that the fact of more single than double hare-lips being operated on is accounted for by the great mortality in the double cases. In addition to the causes of mortality just enumerated, we must also remember that the inspired air is not warmed, as in the natural state of parts, before its entry into the air-passages.]

An early removal of the deformity must obviously be very desirable; but as it cannot be accomplished without an operation attended with some degree of pain, Dionis, Garengot, and others advise waiting till the child is four or five years old, on the supposition that, at an earlier age, the child's agitations and cries would render the operation impracticable, or derange all the proceedings taken to insure its success. It is plain, however, that such reasons are not of great weight. A child four or five years old, and very often even one eight or ten years of age, is more difficult to manage than an infant only a few months old. Every child of the above age has a thousand times more dread of the pain than of the deformity, or of the inconveniences of the complaint to which he is habituated; while an infant of tender years fears nothing, and only feels the pain of the moment.

A more rational objection is the liability of infants to convulsions after operations; and this has induced many surgeons to postpone the cure of the hare-lip till the child is about two years old. This custom is also sanctioned by Sir Astley Cooper, who mentions in his lectures several instances which have either been communicated to him by others, or have occurred in his own practice, where operations for the cure of hare-lips in very young infants have had a fatal termination, in consequence of an attack of convulsions or diarrhoea. The period when dentition is completed, or the age of two years, he therefore sets down as the most advantageous for the operation.

Le Dran performed the operation on children of all ages, even on those at the breast. B. Bell operated with success on an infant only three months old. Muys advises it to be undertaken as soon as the child is six months old. Roonhuysen operated on children ten weeks after their birth,

and all his contemporaries praised his singular dexterity and success. As an essential step to the success of the operation, he recommended hindering the children from sleeping a certain length of time before it was undertaken, in order that they might fall asleep immediately afterwards; and with the same view opiates have been prescribed.

Baron Dupuytren deems it unsafe to operate on newborn children, because their flesh is so soft that the pins readily cut through it, and because general mortality, independent of every particular cause, being at this age greater than at any other period of life, it would be imprudent to augment the chances of death which hang over the young being, by an additional one resulting from the operation. On the whole, he infers, that the best period for operating is when the infant is three months old. (See *Clin. Chir.* t. iv. p. 90—92.)

[More recent experience has led most surgeons of the present day to operate as soon as possible after birth. Dr. P. Frank informs me that he assisted Dr. Wagner to operate on a child two hours and a half after birth. I have done the operation myself four hours after birth, and the infant fell asleep before the application of the suture was completed. Langenbeck, who advocates early operation strongly, says he has frequently seen children fall asleep thus before the surgeon's task is over.]

Quite apart from other considerations, early operation seems desirable on account of the acknowledged influence which closure of the labial fissure exercises in promoting union of the palatine cleft. In the first year of life, the growth of the incisive portion and alveolar process is more rapid than that of the palatine process. Union, therefore, must commence anteriorly, and it is obvious that it must be favoured by the pressure exercised by the united lip, which can then be used for the purpose of suction. Without this pressure, muscular action would evidently tend to increase the breadth of the fissure.]

Putting out of consideration the partial success which has attended the use of blistering plaster, for making the edges of the fissure raw and capable of union, all practitioners entertain the same sentiment with regard to the object of this operation, which consists in reducing the preternatural solution of continuity to the state of a simple wound, by cutting off the edges of the separated parts throughout their length, and then keeping these parts in contact until they have completely grown together. But, although such principles have been generally admitted, there was formerly some difference of opinion with respect to the best method to be followed in practice; some operators having preferred sutures for keeping the edges of the wound in contact, while others disapprove of them, believing that a perfect cure might always be accomplished by means of adhesive plaster and a uniting bandage, so as to save the patient from all the pain and annoyance of sutures.

Modern surgeons do not doubt that a hare-lip may possibly be cured by means of adhesive plaster and uniting bandages, quite as perfectly as with a suture; and they readily allow that the first of these methods, as being more simple and less painful, would be preferable to the latter if it were equally sure of succeeding. But it is far more uncertain in its effect. To accomplish a complete cure, the parts to be united must be maintained in

perfect contact until they have contracted the necessary adhesion; and how can we always depend upon a bandage for keeping them from being displaced? What other means, besides a suture, affords in this respect perfect security?

I shall first describe the operation as usually performed at the present day. It may be divided into three stages. 1. Loosening the lip. 2. Paring the edges of the cleft. 3. Uniting the raw edges.

1. *Loosening the Lip.*—The first thing is to examine whether there is any adhesion of the lip to the gum; and, if there be, to divide it with a knife. Some authors (*Sharp*) recommend the frænulum, which attaches the lip to the gum, always to be divided; but when the hare-lip is at some distance from this part, it will not be in the way of the operation, and need not be cut. On the other hand, when the frænulum is situated in the centre of the division, it should be divided beforehand.

[In separating the lip from the alveolar process, to loosen the parts, *Souper* (*Nouveau Procédé pour le Bec de Lièvre*, Brussels, 1858) is careful to preserve the labial frænum, as he imagines that in after-life the lip loses much of its characteristic expression if the frænum be removed.]

When one of the incisor teeth, opposite the fissure, projects forward, it must be drawn, lest it irritate the parts after they have been brought into contact.

Sometimes, but particularly when a cleft exists in the bony part of the palate, a portion of the upper jaw forms such a projection, just in the situation of the fissure in the lip, that it would render the union very difficult, if not impracticable. In this circumstance, the common plan has been to cut off the projecting angles of bone with a strong pair of bone-nippers. The part was then healed, and the operation for the hare-lip performed. Cutting off the projection of bone leads to a diminution in the diameter of the bone, which no longer corresponds to the lower jaw-bone, and great disfigurement, and even inconvenience in mastication, are the consequences. Hence, *Desault* used to employ simple compression, by which means the prominence was usually reduced in a few weeks, and the opportunity afforded of operating for the cure of the hare-lip. (*Œuvres Chir.* t. ii. p. 207.) Of course the actual necessity of using bone-nippers, or even of having recourse to compression, will depend upon circumstances; for if the prominence of bone be sharp and irregular, no surgeon, I conceive, would hesitate about the removal of such inequalities in preference to the trial of pressure; but a moderate prominence of bone, without any sharp, irritating edges, or angles, will not hinder the success of the operation; and even the propriety of removing teeth must entirely depend upon their being likely, by their direction, to irritate the lip, and disturb the union of the fissure.

One serious objection to cutting away the projection of the jaw is the deformity afterwards, likely to continue during life, from the deficiency of the incisor teeth; and another is the subsequent overlapping of the lower jaw, and its projection beyond the upper one; communicating to the mouth an appearance seen in very old subjects. These were the considerations which have induced me to employ pressure, which is much more conveniently applied by means of a kind of spring truss, adapted to the child's head, than with bandages, which would be seriously annoying, and the right

action of which could not be regulated without the utmost difficulty. When some of the bone must be cut away, on account of its roughness and angular prominences, I advise the practitioner to remove only the irritating points, and afterwards have recourse to pressure.

In a boy, thirteen years old, where the alveolar process jutted forward, M. Gensoul took hold of it with a strong pair of forceps, and brought it into the perpendicular position by main force. This rough method succeeded perfectly. (See *J. F. Malgaigne*, in *Manuel de Méd. Opér.* p. 444, ed. 2.)

[There cannot now be any difference of opinion with regard to the advisability of pressing the prominent inter-maxillary bone backwards. As a general rule it should be done. Its removal is only indicated when it is very imperfectly developed or deformed. The manner of attaining the object is not of great consequence, provided it be obtained. Sometimes it may be pressed backwards by the fingers. Some operators divide the vomer; others follow Blandin's example, who fractured the osseous connection between the vomer and inter-maxillary bones. Langenbeck divides the triangular cartilage of the nose. If any portion of the projecting inter-maxillary bone be removed by cutting pliers, the actual cautery should be applied to the bleeding surface of bone, as oozing of blood is very apt to continue, and has proved fatal.]

2. *Paring the Edges of the Cleft.*—In the operation for single hare-lip, the grand object is to make as smooth and even a cut as possible, in order that it may more certainly unite by the first intention, and be of such a shape that the cicatrix may form only one narrow line. Hence, in this country the edges of the fissure are cut off with a sharp knife. One plan is to place any flat instrument, such as a piece of horn, wood, or pasteboard, underneath one portion of the lip, and then, holding the part stretched and supported on it, to cut away the whole of the callous edge. Another is to hold the part with a pair of forceps, the under blade of which is much broader than the upper one: the first serves to support the lip, the other contributes also to this effect, and, at the same time, serves as a sort of ruler for guiding the knife in an accurately straight line. When the forceps are preferred, the surgeon must of course leave out of the upper blade just as much of the edge of the fissure as is to be removed, so that it can be cut off with one sweep of the knife. This is to be done on each side of the cleft. But at the present day most surgeons remove the margins of the fissure by transfixing the lip with a long sharp-pointed narrow bistoury just above the upper end of the cleft, and then cutting towards the red portion of the lip, while the part is held and stretched by the surgeon himself, or his assistant. One side of the cleft is thus pared off, and then the other; particular care being taken to remove a small piece of the red part of the lip on each side, lest an ugly notch should be left in that situation. This is the plan ordinarily followed by Mr. Liston.

In France, the edges of the fissure are always taken off with a pair of strong, sharp, long-handled scissors, invented for the purpose by M. Dubois. (See *Alf. A. L. M. Velpeau*, in *Nouv. Élém. de Méd. Opér.* t. ii. p. 4; and *J. F. Malgaigne*, in *Manuel de Méd. Opér.* p. 442, ed. 2.) Scissors had an

advocate in Desault (*Œuvr. Chir.* t. ii. p. 179); and B. Bell was also in favour of them.

In cutting off the edges of the fissure, the incision must be carried to the upper part of the lip; and even when the fissure does not reach wholly up the lip, the same thing should be done; for, in this manner, the sides of the wound will admit of being applied together more uniformly, and the cicatrix will have a better appearance. We should also not be too sparing of the edges which are to be cut off. Practitioners, says M. Louis, persuaded that the hare-lip was a division with loss of substance, have invariably advised the removal of the *callous* edges. But, in the natural hare-lip there is no callosity; the margins of the fissure are composed, like those of the lip itself, of a pulpy, fresh-coloured, vermilion flesh, covered with an exceedingly delicate cuticle. The whole of the part having this appearance must be taken away, together with a little of the true skin. At the lower part of the fissure a rounded red substance is commonly situated, which it is absolutely necessary to include in the incision. Were this neglected, the union below would be unequal, and, through an injudicious economy, a degree of deformity would remain. The grand object, however, is to make the two incisions diverge at an acute angle, so that the edges may be put into reciprocal contact their whole length, without the least inequality.

[The next object, after doing everything to secure perfect union by the first intention, is to prevent the formation of an indentation at the free margin of the united lip, just at the lowest point of the united fissure. This indentation is not only a deformity, but it must also impede, to some extent, perfect articulation of the labial sounds. Malgaigne's mode of paring the edges prevents this indentation. He separates a strip from each edge, by carrying two incisions from above downwards, towards, but not through, the free margin of the lip. The two upper thirds of the strip are then cut away, and the lower third pressed downwards and united, forming a projection downwards. Other operators obtain a nearly similar result by making an elliptical incision on each side instead of the oblique cut. The objection is, that infants are apt to suck at the small protuberance remaining at the inferior angle of the united fissure, and loss of blood may thus take place. The method of Langenbeck is perfect in this respect, especially when the fissure is lateral. One side is pared simply, the lower end of the cut curving outwards; the other side is pared almost after Malgaigne's method, and the lower free border, which is not removed, passes over the median line for some distance, and is united with the opposite border. The cicatrix is thus vertical at the upper part and oblique at the lower part, and no contraction of the cicatrix can lead to notching or indentation of the free border of the lip.]

These observations particularly refer to the most simple form of hare-lip, viz. to that which presents only one fissure. When there are two clefts, the cure is accomplished on the same principle; but it is rather more difficult of execution; so that the old surgeons, until the time of Heister, almost all regarded the operation for the double hare-lip as impracticable: only a few described it, with the direction to operate on each fissure, just as if it were single. M. de la Faye operated in

this way with success. (*Mém. de l'Acad. de Chir.* t. iv. 4to.) M. Louis was of opinion that all difficulties would be obviated by doing the operation at two different times, and awaiting the perfect cure of one of the fissures before that of the other was undertaken. Experience proves, however, that it is not essential to perform two operations for the cure of the double hare-lip. Desault found that when the edges of the two fissures were pared off, and care taken to let one of the pins pass across the central piece of the lip, the practice answered extremely well. (See *Œuvres Chir.* t. ii. p. 201.)

Dupuytren had a particular method of operating in some cases of complicated hare-lip. He observed that when the labial tubercle was inserted very close to the point of the nose, its union to the lateral parts drew the lip upwards, and exposed the gums and teeth; while the nose itself was pulled down and flattened in a most ugly manner. Hence he conceived that it would be better to employ the labial tubercle in forming the lower part of the partition of the nose, and to unite at once the lateral portions of the lip. He first divided with a bistoury the fold of mucous membrane uniting the labial tubercle to the osseous one, and then, with a pair of cutting forceps, removed all such portions of the latter as projected beyond the anterior level of the jaws. He next pared off the sides of the cutaneous tubercle and its lower edge. These things having been done, the vertical margin of the fissure, on each side, was cut off with a pair of scissors. The two lateral portions of the lip were now brought together and united with two pins; and then the fresh-cut bleeding middle tubercle was laid over the bony partition of the nostrils, of which it was to form the lower portion. A third pin was applied so as to include at once the upper end of each part of the lip, and the loose extremity of the reflected tubercle. Lastly, two interrupted sutures united the angles of this tubercle to the lateral portions of the lip. The sutures were assisted with strips of adhesive plaster, and a bandage, that made pressure on the apex of the nose, so as to keep the flap from being too much stretched. (See *Clin. Chir.* t. iv. p. 92.)

[Four interesting cases in which this practice has been followed are recorded by Mr. Fergusson. (*Practical Surgery*, p. 572, 573.) Voss, of Christiania, has recently revived the operation *à deux temps*, first uniting one side to convert the double into a single hare-lip, and three weeks afterwards depressing the inter-maxillary protuberance and uniting the remaining fissure. The cases must be very rare, however, in which it would not be preferable to complete the operation at one sitting.

3. *Union of the raw edges* may be effected by ordinary insect needles, or hare-lip pins with glass or wax heads, or silver pins with movable steel points, or by some modification of the quill suture, such as Mr. Brooke's beads, or the metal button of Mr. Wood, of Gloucester; or, lastly, by the simple suture, interrupted or uninterrupted, of silk or of wire.]

Although the generality of surgeons use the twisted suture, Sir Astley Cooper gave the preference to the common interrupted suture, on account of the difficulty sometimes experienced in withdrawing the pins, and the liability of the new adhesions to be broken on the occasion; whereas the threads of a common suture may be cut, and taken

out with the greatest facility. However, as most children cry on the removal of the suture, whether one kind or the other be employed, the only safe plan is not to withdraw the pins or ligatures till three or four complete days have elapsed from the time of the operation, when the adhesions will be tolerably strong; and the cheeks should always be held forward by an assistant, until the plasters, and, if deemed necessary, compresses and a bandage, have been put on.

[At Guy's Hospital, Mr. Cock and Mr. Forster have followed Sir Astley Cooper's practice, but employ the uninterrupted suture. Most surgeons, however, prefer some form of hare-lip pins, believing that union is more certainly attained by their use, and that the objection to the scar at the points of exit and entrance is trivial.] The simplest pin is that used by Dr. Barton, of Philadelphia, who prefers a piece of iron wire, with a point made by simply cutting it with a pair of scissors. Thus he avoids the risk of the steel point slipping off the pin, and remaining within the lip; an accident which Dr. Reese states has often happened. "So many failures" says he, "have occurred from the pins being torn out by the child, or catching in the nurse's clothes, that, if there were no other objection to the use of pins, they ought to be abandoned. Many surgeons in this country [the United States], and among these Dr. Mott, have adopted the interrupted suture in cases of hare-lip, and with the most satisfactory results." Notice is then taken of Sir Astley Cooper's relinquishment of the twisted suture. (See *Dr. Reese's Amer. ed. of this Dict.*)

It is obvious that a great deal of exactness is requisite in introducing the pins, in order that the edges of the incision may afterwards be precisely applied to each other. For this purpose some surgeons previously place the sides of the wound in the best position, and mark with a pen the points at which the pins should enter and come out again. The pins ought never to extend more deeply than about two thirds through the substance of the lip. [The lowest pin should be introduced first, just at the red margin of the lip, and close to the orifices of the bleeding coronary arteries, so that the pressure of the two opposed surfaces may compress the vessels and stop the bleeding. The next pin should be introduced about half an inch above the first; and a third, or even a fourth, may be necessary. A piece of thread or stocking-cotton is then to be repeatedly wound round the ends of each pin, from one side to the other, in the form of a figure of 8, each pin being treated separately. Lastly, the steel points of the pins are to be taken off by a pair of cutting pliers, and collodion may be brushed over the threads until they are saturated with it.

Various kinds of plaster, compresses, and bandages have been used for pushing the cheeks forward and causing the lip to part, so as to take off all strain upon the stitches. By far the best is Hainsby's truss, so strongly recommended by Mr. Fergusson. (*Op. cit.* p. 571.)

In general, the pins may be removed on the fourth day. When collodion has been used, no plaster is required, as the threads saturated with dry collodion adhere for many days, and form excellent splints. When collodion has not been used, or the threads have come off, a strip of plaster may be applied to support a delicate cicatrix.

Mr. Allen Duke (*Lancet*, 12 March 1858) re-

commends the use of internal sutures to secure union of the mucous membrane, and his practice has been followed by others; but it is not to be recommended, as these internal sutures irritate the infant unnecessarily.

If union by first intention fail, the granulating edges may be brought together again, either by suture, or by careful application of the truss and plaster; and good union is frequently obtained in this way after apparent failure.

During the first few hours after operation, it is always necessary to be on the watch for quiet insensible hæmorrhage into the child's mouth. A good deal of blood is often swallowed, and melæna is frequently observed after hare-lip operations. In those cases where young children have been said to die of "convulsions" after these operations, the convulsions have most probably been hæmorrhagic.]

The pins should be introduced at least two thirds of the way through the substance of the lip, lest a furrow should remain on the inside of the part which might allow pieces of food to lodge in it. There is, however, a stronger reason for attending to this circumstance, viz. the hæmorrhage which may take place when it is neglected. As soon as the edges of the wound have been brought together by means of the suture, and the pins are properly placed, the bleeding ceases; but when the pins have not been introduced deeply enough, and the posterior surfaces of the incisions are not applied to each other, the blood may continue to run into the mouth, and give the surgeon an immense deal of trouble. In the memoir written by Louis there is a case in which the patient died in consequence of such an accident. Persons who had undergone the operation were formerly advised to swallow their spittle, even though mixed with blood, in order to avoid disturbing the wound by getting rid of it otherwise. In the case alluded to, the patient, who had been operated upon for a cancerous affection of the lip, swallowed the blood as he had been directed to do, and he bled so profusely that he died. On the examination of the body, the stomach and small intestines were found full of blood.

When there is a fissure in the bones forming the roof of the mouth, it usually diminishes, and gradually closes, after the hare-lip is cured. But this does not always happen; and when the parts remain so considerably separated as to obstruct speech and deglutition, or cause any other inconvenience, a plate of gold exactly adapted to the arch of the palate may sometimes be usefully employed. In such cases dentists usually fix the plate of gold by means of springs of the same metal. Platina, which is cheaper, might be used for the same purpose. [The subject, however, of artificial palates is one on which much mechanical ingenuity has been usefully exerted, especially of late, since the hardened rubber called vulcanite has been used by dentists. Mr. Parkinson has published some interesting cases, showing how admirably this substance may be employed for artificial palates. Fissure of the soft palate may be closed either by operation, or by the addition of a sort of curtain of rubber to the vulcanite palate. (See PALATE; STAPHYLOGRAPHY.)

In cases where the notch or indentation has been allowed to remain after the cure of hare-lip, it may easily be remedied by paring off the red margin of the lip on both sides and uniting the raw surfaces accurately. The mucous ring formed by the lips

is so extensible that this proceeding is very easy and successful.]

HEAD, INJURIES OF THE. [Under this division are included all injuries affecting the scalp and pericranium, the skull itself, the membranes of the brain, and the encephalon.

The position of the human cranium at the summit of the spinal column, and the remarkable structure and arrangement of its bones, afford evidence of an all-wise provision against external injury; but its exposed position renders it liable to accidents from which no foresight could have protected it. The pulpy tissue of which the brain is composed is obviously predisposed to concussion, contusion, and laceration, from the unyielding nature of its bony walls, and this predisposition to injury increases as the skull becomes consolidated by growth; nevertheless the effects of external violence are very materially modified, by the elasticity and springiness of the processes of the *dura mater*, which are interposed between the segments of the brain, and by the soft cushion of cerebro-spinal fluid on which this delicate organ rests.]

INJURIES OF THE SCALP.

[In this article will be considered, first, injuries of the scalp. The scalp is composed of the following tissues arranged in strata. The common integument constitutes the first layer; this is comparatively inelastic, and connected to the subjacent tendon of the occipito-frontalis muscle by aponeurotic slips, in the interspaces of which is found a large quantity of firm granular fat: numerous blood-vessels and nerves are distributed upon it, and it is endowed with a high degree of sensibility. Beneath this lies the occipito-frontalis muscle with its broad flat tendon stretched between its anterior and posterior muscular bellies. Laterally are the temporal aponeuroses and the temporal muscles.

The occipito-frontalis is loosely connected with the external pericranium by a distinct layer of cellular membrane, in which also are distributed innumerable small vessels. The intimate connection between the skin and the occipito-frontalis tendon is not without its interest in a surgical point of view, for it explains the fact that in extensive lacerations of the scalp it is rare that a part of any magnitude becomes completely detached; and as, from the same cause, the skin cannot retract after laceration, the edges of the wound are easily retained in apposition after they have been readjusted. A close sympathy between the various strata which compose the scalp results from the union of their blood-vessels,—a sympathy which from a similar cause exists between the pericranium and the bones, and between the bones and the dura mater: thus a continuous sympathy may be traced between the surface of the scalp and the cerebral meninges.

Contusions of the Scalp.—Independently of ordinary bruises, to which this part is obviously very liable, there are two forms of contusion of considerable interest, and which vary materially in their character and result: thus it happens that in bruises of the scalp effusion of blood occurs in some cases beneath the tendon of the occipito-frontalis to an enormous extent, whilst in others the effusion is limited to a circumscribed space, and from its peculiar position assumes a shape and condition which often lead the inexperienced to an entire misconception of its true character. There is scarcely any limit to the extent of the extravasation beneath the tendon of the occipito-frontalis: every surgeon of experience can bear witness to the truth of this assertion. We have seen the scalp raised up in the form of a soft undulating bag extending on either side as far as the zygoma, and protruding the skin of the forehead so as to produce a deformity in this direction which totally altered the outline of the features. Experience leads us to believe that these extensive effusions are more common in children. The effusion is occasionally bounded by an irregular line of coagulum which seems to limit its extent. Such effusions under simple treatment usually disappear in a few days, but occasionally partial suppurations occur, necessitating more active surgical interference. Rest, slightly elevating the head, cold applications, gently supporting but not compressive bandaging, comprise the category of external remedies; whilst free purging and a moderately anti-inflammatory regimen, succeeded by a more generous diet, are necessary to promote absorption of the effused blood. It happens occasionally that a portion remains unabsorbed for weeks; nevertheless it is better to abstain from cutting the scalp, unless a blush of inflammation indicates approaching suppuration: the formation of matter may be advantageously anticipated by an early opening.

When effusion of blood takes place in the meshes of the condensed tissue connecting the skin to the tendon of the occipito-frontalis, its extent is more limited, but it gives rise to a very remarkable condition. When the part is examined the impression communicated to the fingers is as if the surface of the scalp were depressed into a cuplike form: this is most probably due first to the limited extent of the effusion, and next to the imperfect coagulation of the blood,

the centre being in a fluid state. Such cases may be mistaken for depressed fracture of the skull: the diagnosis is, however, very easy. If the thumb-nail is firmly pressed against the margin of the apparent depression an indentation is made, whilst if the bone is really depressed no impression can be made on it in this manner. It certainly happens that cases occasionally occur of such ambiguity that a surgical exploration is quite justifiable, even where the cupping arises from effusion of blood; for although no surgeon, in the absence of symptoms of pressure on the brain, would willingly cut through the coagulum to the bone for the purpose of examining the skull, yet if symptoms of pressure, however obscure, exist, he has no alternative, but must make an incision, as a fracture may be found beneath the extravasation, and effusion of blood upon the dura mater may be detected under the fractured bone. We have seen many instances of this. The local and general treatment for the relief of these limited effusions is similar to that recommended in the preceding class of cases, but bandages may be dispensed with. The effusion will be found generally in the meshes of the subcutaneous cellular tissue. We have verified this statement by necessary explorative incisions during life, and by post-mortem examination. Similar appearances may no doubt result from extravasation into the loose cellular membrane connecting the occipito-frontalis and the pericranium. In some severe contusions of the scalp a distinct pulsation may be detected in the centre of the bruised part: this arises from a rupture of numerous small arterial branches, and generally ceases after a time under the employment of ice and pressure. But a distinct small spurious aneurism is formed occasionally, requiring pressure for its cure; and if this fails it may be transfixed with pins and tied, or it may be incised and the wounded vessel sought and tied. We witnessed a doubtful case of spurious aneurism of the posterior branch of the temporal artery cured by the latter method: the aneurismal dilatation was very distinct, but there was some doubt as to whether a branch of the temporal artery had not been punctured.

In all cases of severe contusions of the scalp there is a great risk of suppuration beneath the tendon of the occipito-frontalis. When matter is formed, however limited the extent of the collection, it should be let out at once by a free pendent opening made through the tendon, the larger branches of the arteries being avoided. When suppuration occurs as a consequence of injury to the pericranium, the bones themselves may die; and, further, as a result of the continuous sympathy established between the parts, matter may be formed on the surface of the dura mater.

Of Punctured Wounds of the Scalp.—A puncture may penetrate all the tissues of the scalp: the generality of such cases usually soon get well under simple treatment; but it often happens that erysipelas supervenes, especially in persons who have led a debauched and irregular life, and this may be followed by sloughing of the occipito-frontalis tendon, or, as is much more common, by abscess. The characters of this form of inflammation are elsewhere considered, and the treatment to be pursued for its cure is so fully discussed that we forbear to make any further especial allusion to the subject. Although we cannot hesitate to admit that

in these cases there is much risk of inflammation attacking the membranes of the brain or the brain itself, nevertheless experience leads to the belief that the principles of treatment which ought to guide our practice here differ in no material respect from those which are usually employed in the management of cases of traumatic erysipelas wheresoever existing. Pott and others have attempted to define the symptoms characterising the inflammation as it attacks the separate tissues of the scalp; but much importance cannot be attached to this point, as in most cases all the strata of the scalp are simultaneously affected.

Incised Wounds of the Scalp require few special remarks: they vary in extent and depth, and are frequently accompanied by troublesome hæmorrhage when in the vicinity of the large arteries. As in the management of incised wounds in any other part, the surgeon's attention should be directed first to the arrest of the hæmorrhage, and pressure may be conveniently applied over almost any part of the skull for this purpose. We have a strong predilection for the ligature in all cases of bleeding where the ligature can be used. In hæmorrhage from wounds of the scalp, there is occasionally much difficulty in the application of a ligature; but generally this may be accomplished, especially in cases of recent wound, as the divided end of the artery can usually be seen projecting from the skin, into the dense structure of which it cannot retract: it may then be seized with the forceps, or a hook, and tied. When the bleeding has ceased the wound should be accurately adjusted with strips of simple plaster, and a retentive bandage should be applied.

With respect to the employment of sutures in wounds of the scalp, there need be no serious apprehension of any risk of erysipelas resulting from their use; but, as the scalp is but slightly elastic, and as there is consequently no disposition to retract after division, there can be no necessity for the use of sutures, unless under the extraordinary circumstances of extensive wounds, where large pendulous flaps hang loosely, and cannot otherwise be conveniently retained in apposition. These remarks apply to lacerated rather than to incised wounds. Incised wounds vary in extent and depth, and it can readily be believed that cases occurring in military practice are generally of far greater extent and importance than those which surgeons are in the habit of seeing in hospital or private practice: but all bear equal testimony to the fact of the ready curability of such cases, however extensive, by careful means, especially in healthy constitutions. Absolute rest in bed, with free purging, and the application of cold after the head has been shaved, are to be steadily enjoined, and we need fear no unfavourable result.

Lacerated wounds of the scalp vary in extent according to the force applied; but they have an undoubted tendency to assume a rectilinear direction. Wherever they are very extensive, the occipito-frontalis tendon is lacerated and raised with the integument. The most extensive wounds of this description we have ever seen have been those caused by the machinery used in our large cotton-mills; and they frequently happen in consequence of the long hair of the female operatives becoming entangled whilst the machinery is in rapid revolution. The extent of the laceration under such circumstances can be readily imagined. The entire scalp is sometimes com-

pletely torn away, or is left hanging by a slender piece of skin. But it fortunately happens that in such cases the pericranium is left entire. We have seen the whole surface of the calvarium, as well as the temporal fascia, the seat of healthy florid granulations after an injury of this description. These wounds eventually cicatrise completely. The scalp frequently becomes detached by falls upon the ground, or by the passage of heavy carriage-wheels over the side of the head. In such cases dirt, gravel, and other foreign bodies, are ground into the edges of the wound or beneath the pendulous flaps of skin, and the scalp is bruised so as to appear thoroughly spoiled. Troublesome hæmorrhage frequently attends extensive lacerations of the scalp, but it is occasionally absent. Hæmorrhage occurs from the torn arteries at the edge of the wound, and now and then it arises from the lacerated blood-vessels in the cellular tissue beneath the occipito-frontalis tendon. Although absent in the first instance, its occurrence is always to be apprehended after an accident and during the progress of the case, if suppuration and gangrene attack the part.

The treatment of lacerated wounds of the scalp is highly important, yet the principles of conduct are comparatively simple. If there is much bleeding, or indeed any hæmorrhage, pressure should be tried, or the bleeding vessel must be sought for and tied; a ligature on the proximal end of the divided artery is sufficient. When there is no hæmorrhage at the time, it is better by the use of the sponge rather to encourage it than to leave the case with a risk of its occurring at a more unfavourable season. The source of hæmorrhage from the subjacent vessels is also to be sought for by carefully everting the torn scalp, and if the hæmorrhage be severe and difficult of control by pressure, it is advisable to make a free incision in the direction of the bleeding artery, and thus expose it. Pressure, if carefully and accurately applied, will usually suffice to stop all bleeding from the torn subjacent arteries; but, if the hæmorrhage continue, it may distend the scalp to a very great extent, and the artery must then be sought for and tied. There is nothing more embarrassing than the frequent recurrence of hæmorrhage in scalp wounds; amongst other modes of treatment, we have occasionally seen troublesome bleeding effectually arrested by the careful employment of the clamp tourniquet: of course this could not well be used in cases where the hæmorrhage arose from a wound of the scalp on the vertex of the skull, but the screw tourniquet could be used under such circumstances. We have spoken of the paramount necessity of directing attention first to the hæmorrhage: the next important point to attend to is the cleansing of the wound from all foreign bodies; but it is scarcely necessary to insist on this essential piece of simple surgery as especially requisite in wounds of the scalp. Having therefore carefully cleaned the wound, the hair being first shaven off, the separated parts are to be readjusted with the nicest accuracy. No part of the lacerated scalp, however damaged, is to be removed. We should not have alluded to this point had we not witnessed, within the last twenty years, a case where a surgeon had removed the whole scalp from a patient, which was hanging by a slender piece of skin: he had thus severed the only connecting medium of vascularity in a part which might have continued to live, and which by

careful treatment would probably have again adhered to the surface of the calvarium. We cannot doubt that such barbarous surgery is now wholly exploded. There is no part of the body which adheres so readily to the subjacent parts as the scalp, and there are few parts which have so slight a tendency to slough after contusions, a condition evidently resulting from its great vascularity. If the surgeon prefers the suture, the parts may be kept together by interrupted sutures of silver wire or common silk, after which either strips of mild unirritating plaster may be laid down at intervals, or lint dipped in warm water may be employed, if the surgeon apprehend sloughing from the bruise the part has sustained. We are very averse, in the coaptation of lacerated wounds of the scalp, to the use of small pieces of adhesive plaster, so sedulously applied that no opening is left for the escape of blood and matter: it is far better to apply strips of plaster with intervals between them, leaving open spaces here and there, and to retain the whole by gently supporting bandages, over which wet lint may be lightly laid. We readily adopt the doctrine laid down by Pott, that sutures are highly advantageous in many cases of extensive and irregular lacerations of the scalp, although we are equally averse to their indiscriminate employment, as being in a vast majority of cases unnecessary. We do not recollect a single instance in which erysipelas could be fairly ascribed to their use. Lint soaked in warm water is preferable to cold applications where there is any risk of sloughing, but in a great many cases it is a matter of comparative indifference to which the preference is given. The dressings should not be renewed in less than forty-eight hours, and if there is no evidence of suppuration a much longer period may elapse before their renewal; but it is wrong to allow them to remain very long, particularly where, from the known or suspected habits of the patient, erysipelas may be expected. There is one thing the surgeon should be prepared for after extensive detachment of the scalp, namely, a partial union of the edge of the wound with suppuration beneath the detached scalp: this is attributable to the retention of slight effusions of blood. The matter must be pressed out through the wound, and compresses and bandages should be carefully applied; or it will become necessary to incise the scalp in dependent parts, taking care to avoid the track of large blood-vessels. Portions of the occipito-frontalis tendon often slough, especially when there has been much contusion of parts, and suppuration often results from this cause; therefore, if it is necessary, as is frequently the case, to give exit to the matter by incision, the surgeon should after the evacuation of the pus use gentle pressure with a sponge, and any piece of dead tendon may be carefully removed by the forceps, and thus a continual source of irritation will be at once removed. After the removal of all sloughs a bandage should be employed to retain without undue pressure the scalp in apposition with the subjacent parts, and a complete union will often be found to have occurred even in cases where the subjacent bone has been denuded of its pericranium.

By persisting steadily in this simple method, most extensively raised portions of scalp are found to unite completely to the subjacent parts, and at the edges of the wound; and the surgeon, as

well as the patient, is astonished at the rapidity and completeness of the cure. It hence becomes an axiom in surgery, in the treatment of contused and lacerated wounds of the scalp, on no consideration whatever to remove the smallest portion of the damaged integument; and a favourable prognosis may generally be safely advanced. The modern improvements in surgery are in no class of cases more perceptible than in these; and much credit is due to the surgeons of the French and English schools for substituting this simple treatment for the barbarous mutilations of the older surgeons, who appear to have endeavoured rather to see how large a portion of the scalp they could sacrifice than how much they could save and restore to a sound condition. We cannot assent to the indiscriminate censure which has been passed on Pott's writings in reference to this subject. There is no doubt that in Pott's time it was the custom to cut away large portions of bruised scalp, but he distinctly cautions his readers against doing too much in this respect.

The constitutional treatment in lacerated scalp wounds must be strictly attended to. Abstractedly, the general treatment is the same as in similar wounds in other parts of the body, and may be comprised under the head of mild antiphlogistic treatment, with careful attention to the state of the bowels, to be followed by generous support. In cases which come under the notice of hospital surgeons in this metropolis, it is very undesirable to diminish the constitutional powers by low diet and depletory measures; but it may be requisite to modify our plans if there is much fever, and especially in cases of young and vigorous subjects, whose constitutions have received no injury from irregularities in diet, &c.: under this condition a more strictly antiphlogistic regimen must be enjoined at first, to be succeeded by more liberal diet and tonics when suppuration has once been established.

The liability to attacks of simple erysipelas in cases of wounded scalp has already been spoken of; and before quitting this subject we cannot too strongly advise the strictest attention to quietude and rest so long as any scalp wound remains unclosed. After the opening of abscesses, whilst wounds are discharging, exposure to a cold north-easterly wind often induces fatal erysipelas. We have witnessed these attacks so frequently, that in hospital practice we never allow a patient to leave the ward before the wounds are completely closed. There appears to be a peculiar predisposition in the scalp and face to a repetition of attacks of erysipelas, and such attacks, if repeated, are frequently fatal.

Erysipelas also of the phlegmonous character, where, indeed, all the tissues external to the cranium are involved, occasionally sets in; and, the disease extending even through the bones of the cranium by continuous sympathy, the dura mater and membranes of the brain, and even the brain itself, become simultaneously affected. So also the cellular tissue of the neck and chest, the pleuræ and pericardium, may become the seat of a similar disease from an extension of the inflammation; and we have witnessed a fatal result from effusion into the pleura and pericardium. Mr. Hewett (*Medical Times and Gazette*, vol. xl. 1855) mentions similar cases, and we can confirm Sir Benjamin Brodie's remarks by our own experience, that such a condition is frequently co-existent with disease of the liver or kidneys, or both; and there can be no doubt that in some instances it may be fairly attributed to

that fatal form of blood-poison now recognised under the term pyæmia.

Contused Wounds of the Scalp.—Our remarks have been thus far confined to cases of lacerated wounds of the scalp, and there is little to add on the subject of contused wounds: in fact, our observations on the latter class of cases have been in a great measure anticipated, for many of the most serious forms of lacerated wounds are accompanied by a great degree of contusion. It will necessarily happen that where the scalp is much contused there is a greater liability to slough than in the preceding class of cases, and, where sloughing occurs to any extent, there is a risk of troublesome hæmorrhage. The local treatment requires some modification, as the employment of pressure at the part, and cold applications, are inadmissible; but sutures and light warm-water dressings may be used with a greater probability of success. Hæmorrhage also, which is very apt to occur during the sloughing process, may become exceedingly troublesome, and can rarely be arrested by pressure: indeed, pressure to the part the seat of hæmorrhage would only tend to increase the bleeding by favouring the sloughing process. Under such circumstances, and where it is difficult to recognise the source of the hæmorrhage, we may adopt the plan pursued under somewhat similar circumstances by Mr. Hewett, who carefully pressed upon each main artery of the scalp in succession, and thus discovered the trunk whence the bleeding proceeded, and then, by the application of pressure on the trunk itself, he succeeded in arresting troublesome hæmorrhage. If pressure does not stop the bleeding, a free incision must be made through the sloughing to the sound scalp in the direction of the bleeding vessel, and the artery must be secured with a ligature.]

CONTUSION OF THE BONES.

[In considering all doubtful injuries of the cranial bones, the surgeon must take into account the varied degrees of thickness and solidity in the crania of different individuals, for it is well known that there is great difference in this respect, and that, if we examine carefully a large number of calvaria, we shall probably not find two exactly of the same thickness. This is well understood by all practical anatomists, and suggests at once a cause for the great diversity in the consequences of contusions of the skull in different persons. The comparative thickness and elasticity of the bones of children, and especially of infants, should also be well considered; nor ought the different degrees of thickness in different regions of the same skull to escape our observation. Contusion of the bones may happen without laceration of the scalp, or any detachment of the pericranium or dura mater, and such contusions are often followed by very serious consequences. In severe cases the pericranium is broken up or detached altogether, as where a bullet directed obliquely against the cranium has traversed a large extent of the exterior of the skull, and made its appearance at a spot remote from the point at which it had penetrated the scalp: the pericranium then suffers much contusion, and is generally detached to a greater or less extent. In military surgery such cases are not uncommon.

However severe the contusion, the bone may still retain its vitality, and the scalp may reunite to the subjacent bone, even if the pericranium itself is detached; but if the dura mater is at the same time separated from the bone, the latter necessarily perishes. The surgeon, however, in the absence of symptoms of cerebral mischief, endeavours to procure a speedy reunion, where the scalp is raised, by a careful adaptation of the parts; and, in young and healthy subjects especially, further inconvenience need not be anticipated. If, however, suppuration occurs beneath the scalp over the contused bone, as, for instance, in the track of a ball, death of bone generally happens, and the surgeon expects its exfoliation. Necrosis may nevertheless be still confined to the outer table of the skull, and may take place only to a trifling extent; but, in old and cachectic subjects, death of bone frequently happens after contusion, and repeated attacks of erysipelas, gradually diminishing the already enfeebled powers of the patient, protract the cure indefinitely, or lead to fatal suppuration on the dura mater. The treatment of contusion of the bones of the skull should be mildly anti-inflammatory at first, to be followed by generous and even stimulating diet, and no local applications are preferable to the constant use of warm-water dressings.

Contusion of the skull-bones may be limited to the external table, or it may extend to the diploe, or it may involve the inner table of the skull at the same time. So also necrosis, as the result of the injury, may be limited to the outer table, or it may involve the inner table simultaneously. In by far the greater number of cases the outer table is alone affected, and the dead portion becomes readily separated by the agency of the adjacent living vessels, assisted materially by those of the diploe. This latter part, being very vascular, becomes a very important agent in the separation of the outer table of the skull, for the granulations springing from it may be seen almost to lift the dead portion from the subjacent part, and thus assist its removal; or it may be sometimes seen that irregular apertures are made through the dead bone, and, the granulations shooting through these openings, a gradual crumbling takes place, by which the dead part is removed without any decided exfoliation.

The death of the inner, which often accompanies that of the outer, table seldom takes place to the same extent. The fact is not uninteresting, as in some measure illustrating the cause of death of the inner table, which we believe to arise frequently in consequence of its vascular communication with the dura mater having been broken up at the time of the accident. In the examinations which we have made after death in cases of severe contusion of the bones with fatal injury to the brain, we have frequently seen very slight effusions of blood between the bone and the subjacent membrane at the seat of injury; and there is no doubt, although it often happens that such limited effusions are absorbed and the bone lives, that this is not invariably so, and the inner table occasionally dies from being thus deprived of its source of nutrition from the meningeal vessels. That the inner table dies also, as a consequence of the extension of the injury from without, there can be no doubt whatever.

In cases of contusion of the bones of the skull, with effusions of blood beneath the scalp,

it was formerly the custom to make free incisions through the scalp down to the damaged bone, to prevent inflammation and its consequences, and in some parts of the skull, as in the temporal regions, this was considered especially desirable; but the practice is obsolete, and no surgeon would, in the absence of cerebral symptoms, consider himself justified in wilfully mutilating the scalp, and laying bare the contused bones, unless there were other reasons than those of an anticipatory character to justify this procedure. But after severe contusion, thickening of the pericranium to a limited extent occasionally remains, and this is accompanied by pain on pressure, severe headache, and symptoms of great constitutional irritation, and even epileptic convulsions have been distinctly traced to such a cause: under these circumstances a free incision through the pericranium to the bone itself is often followed by the happiest results, and all further mischief is prevented. We have also occasionally seen much benefit from incisions where the pericranium has been more extensively implicated, as in deep-seated inflammation of the scalp, involving the pericranium, and attended with fever, headache, and a sense of great constriction. There is one precaution requisite in incising the pericranium under such circumstances, namely, the avoidance of the large branches of the arteries of the scalp, as no advantage is gained by the loss of much blood. The relief appears to arise from the removal of the tension of the part by the incision, and by the escape of a moderate quantity of blood.

In many cases of contusion fatal inflammation attacks the bones, and extends to the membranes of the brain and the brain itself, long after the original injury. We quote from the writings of Pott two illustrations of this:—

“An elderly woman riding in a hackney coach, by a sudden jolt struck her head with great violence against an iron hook at the top of it. The blow gave her exquisite pain at the time, but that soon ceased, and as it caused neither wound nor tumefaction she took no further notice of it. At the end of near two months she was seized with a violent pain in her head, so violent that for several nights she was obliged to have recourse to laudanum, in order to obtain a little broken rest. In about a week the pain went off, and a tumor arose just where she had been stricken, that is, just in the middle of the sagittal suture. I opened the tumor and discharged a considerable quantity of discoloured and very offensive matter. I passed my finger into the opening, and to my great astonishment found it touched the dura mater. I removed a circular piece of the scalp, and found the two ossa parietalia bare, and carious for a considerable extent on each side of the suture; and in the middle of this carious piece, just in the track of the suture, a hole large enough to admit easily any man's forefinger without touching the edges of the bone. The dura mater lay at a considerable distance from the skull in that part: the discharge from within was very large and offensive, and about three months from the time of the accident she died suddenly in a kind of fit.” (*Pott's Surgery, by Earle, vol. i. p. 115.*)

“A sailor, in an engagement, received a severe blow on the head by a large splinter: a small wound and a considerable bruise were the consequence, but they were so soon well that the man did duty in a few days. At about seven weeks'

distance from the time of the accident, he began to complain of great pain in his head, which pain rendered him so incapable that he was put into the hospital at Gosport. He remained there about three weeks, frequently but not constantly in pain, and during that time had three or four fits of an epileptic character. He was now sent to St. Bartholomew's Hospital, where, having mentioned the circumstances of the blow, I was requested to examine him. There was not the least degree of swelling or inflammation, no mark or vestige of scar, nor any elevation of the scalp, or fluctuation under it. While I was examining his head, he had a slight attack of spasm; but on my desisting he became easy and tranquil. The circumstance of this attack, while I was pressing upon the part, did not at that instant strike me as worthy of notice; but upon reflection it appeared much so. The next day I made the same experiment with the same effect; that is, upon hard pressure he became convulsed, which convulsion ceased upon removing the fingers, but was followed by a rigor. On the following day I ventured to repeat the experiment; but the man was so immediately and so terribly convulsed that I determined never to try it again. It was agreed in consultation that, considering the inefficacy of all that had hitherto been done, and what had lately happened, the most probable method of attempting his relief would be by denuding and perhaps perforating the cranium, in the place where the pressure produced so strange an effect.

“The next day I removed a circular piece of the scalp, and found the pericranium not of a healthy or sound colour, nor adherent to the bone. The bone was carious, and had several small holes in it through which a sanies rose and fell, according to the motion of the blood in the brain. I applied a large trephine, without any regard to the suture, and removed a piece of skull. During the time of the operation the poor man suffered greatly from spasm; but, that over, he became easy and quiet. The dura mater was detached from the skull, and had matter on its surface which was extremely offensive. The ensuing night he passed ill, and the next day had such a rigor, that I verily believed it was the last trouble the man would have. The day after this I found him vastly better: the discharge had been large, but he had not suffered any return either of spasm or rigor, and his principal complaint was extreme lowness.

“Everything for several days wore a favourable aspect. On a sudden he was seized with all the symptoms of a peripneumony, and on the third day from that seizure died. No apparent cause of mischief was found either within or on the outside of the head; the dura mater was well incised, and no lodgment of matter was seen.” (*Op. cit. p. 119.*)

Persistence of fixed Pain in the Head after injury to the Bone.—Quesnay (*Memoirs of the Royal Academy of Surgery of France*) has collected together many cases in which, after contusions of the bones of the skull, pain has continued in distinct spots of the cranium, leading eventually to the necessity of applying the trephine. In some cases the bone has been found much condensed in texture; in some no evidence of disease has been recognised, whilst in others the disease has been eventually discovered after death in the brain or its membranes. We shall briefly refer to a few instances

mentioned by Quesnay. M. Marechal was called to a girl who some time before had received a blow upon the head, which was speedily cured, except that a fixed pain remained over one of the parietal bones. It increased to such an extent as to give rise to fever, which was relieved by bleeding and other appropriate remedies. But the pain having existed for some years, M. Marechal deemed it prudent to apply the trephine. He easily discovered the seat of pain, and on sawing through the bone he remarked that it had the appearance of bone which had been long buried. The pain never reappeared. Morel also operated on two cases with the same result; but the pain depended in the first on suppuration beneath the bone, and in the other nothing particular was observed. In a case operated on by M. Vacher, the disease depended on a fungoid condition of the cortical substance of the brain, the fungi adhering to the dura mater, and the bone was thinned so as to resemble a sheet of writing-paper.

M. Gervais operated on a girl who had some time before received a blow on the back of her head, which left a fixed pain in the occipital region. Whenever the part was violently handled, syncope invariably followed. On cutting down upon the bone the pericranium was found detached, and the bone carious; it exfoliated, and all the symptoms ceased. Scultetus mentions a case of a child seven years old, who fell upon the forehead, and suffered afterwards fixed pain and convulsions. Four months after the accident an opening was made in the spot, and the bone was found dead beneath: the bone was *rugined*, and, healthy granulations springing up, a cure was speedily accomplished. Forestus also operated in like manner on a similar case, and with the same result. Some further observations are recorded by Quesnay to prove the efficacy of trephining in some cases of epilepsy, where the bone was the seat of the cause of the disease, or where matter was found beneath, to which we must refer the reader. (See also *Guthrie, On Injuries of the Head*, in which some cases of this description are related from various sources.)

Mr. Curling performed the operation lately on a young man the subject of epileptic fits, and where pain was experienced on firm pressure at the part: no benefit eventually resulted. The bone presented no positive signs of disease.

The effects of contusion are generally limited to the immediate seat of the injury, but the two following remarkable instances are mentioned by Hewett (*loc. cit.*) in which most extensive disease of all the skull-bones resulted from local contusion.

"A woman æt. 48 fell down a stair and received various injuries, one on the head, which confined her to bed for some days. From this time her health was bad; she complained of fixed pain in the head, and had a disordered state of her stomach and bowels. She was able, however, to attend to the ordinary duties of her family till about three weeks before her death, when she was seized with fever and outrageous delirium. These symptoms subsided after a bleeding; and next day she had erysipelas of the face, which went off in a few days. She was then able to be out of bed, but complained of a fixed and deep-seated pain on the right side of the head, a little above the ear, and there was a discharge of matter from the right ear. She continued in this state, sitting up part of every day,

till three days before her death, when she became comatose with partial paralysis of the left side, and frequent convulsive motions of the right arm. She died on the third day after the occurrence of these symptoms.

"The cranium was very easily opened, the bones being remarkably soft. On raising the skull-cap, the inner surface of the whole upper part of the cranium exhibited a singular state of disease. The inner table seemed to be wanting through its whole extent, and there appeared the rough, irregular, and cancellated structure of the central part of the bone. Betwixt this surface and the dura mater there was the deposition of an adventitious membrane of a yellowish colour, varying from one twelfth to one eighth of an inch in thickness. In raising the skull-cap, this membrane, in some parts, adhered to the dura mater, leaving exposed the irregular cancellated structure of the bone; and, in other places, it adhered to the bone, exposing the dura mater, of its natural appearance. The parts affected by this singular state of disease were the frontal bone above the orbits, the whole of both parietal bones, the squamous portion of both temporal bones, and rather more than the upper half of the occipital bone. The greatest erosion was on the parietal bone, where several portions were very thin and transparent, and a few points were perforated. The external surface of the cranium was of a natural appearance, except at a few points where the erosion had perforated the bones by very small apertures. The immediate cause of death was an extensive abscess, probably recent, which was found in the lower part of the right hemisphere of the brain."

The next case alluded to is recorded by Mr. Drummond. "A sailor having fallen down a flight of stone steps received a contused wound of the scalp on the left side of the occipital bone. Some time afterwards a large piece of the bone was found denuded of its periosteum; he had repeated attacks of erysipelas, and within the space of six years he lost about five square inches of the right side of the frontal, parietal, and squamous part of temporal bones; the whole of the occipital to within a short space of the foramen magnum had disappeared, except a portion of the centre, of about two square inches, which was detached and movable. A large portion of the left side of the frontal, parietal, and temporal bones was in a state of caries, and a portion of the posterior part of each parietal bone remained as a slender arch over the vertex. The man is now alive and in good health. In neither of the cases just mentioned does there appear to have been any indication of a syphilitic constitutional taint."

There is something very unusual in both cases, which implies a most unhealthy state of constitution; for it generally happens that the death of the bone is limited to the immediate seat of the original injury, and the process of exfoliation is confined to this part, without extending in any degree to the adjacent bones, whilst in the cases just quoted a slow and insidious disease had been set up, which led to the gradual and irregular destruction of a very large portion of the bones which form the vault of the skull, although it does not appear to have been confined to this part. At any rate, whatever the true explanation of the occurrence of these phenomena may be, the cases are highly interesting, as showing to what extent disease originating in local injury may proceed, and for how long a time it may continue. Hence the necessity of

using the greatest precaution in the treatment of all cases of contusions of the skull cannot be too strongly insisted on, and our prognosis should be always guarded.

Mr. Hewett has also alluded in his lectures to a remarkable case of hypertrophy of the cranial bones as a consequence of a severe contusion: the case is here quoted in his own words. "A master-builder, æt. 50, slipped from a scaffold from fifteen to twenty feet high and struck his head violently, receiving a severe concussion of the brain. All symptoms of cerebral mischief disappeared in a few days; but, some time after his recovery, this man found that he began to have some difficulty in getting on the hat he had been in the habit of wearing: the enlargement of his skull went on increasing, so much so, that he was obliged to have a new hat made; and from this period, from time to time, he found it necessary to have the size of his hats increased. The enlargement of his skull went on increasing. He suffered no inconvenience beyond the increased size of his head, and died at the age of 70, twenty years after the accident. His head was examined, when it was found that the great size of the head was altogether due to a diseased condition of the bones, which was all but limited to the vault, the base presenting very little alteration in its appearance." (Loc. cit.)

The diseased calvarium is preserved in the Museum of the College of Surgeons. In some parts the bones are nearly an inch, and are in no part less than half an inch in thickness. The circumference on the outside from the nasal eminence to the occipital protuberance measures 26 inches; that on the inside 21. All traces of the compact table of the bones have disappeared, the whole structure being reduced to a fine cancellous tissue, with cells for the most part very small, and irregular in form. The outer surface is perfectly porous, as if pricked with small pin points. The inner surface is permeated by large deep channels for the meningeal arteries. The brain and its membranes were perfectly healthy.

After exfoliation of portions of the bones of the skull, and after the removal of bone by the trephine, the interval is filled up by a tough ligamentous substance, in which minute bony spicula here and there appear, or by a thin layer of bony matter. There is no doubt that in some cases a complete closure of the opening occurs by bony matter gradually pushed forwards from the edge of the sound bone. This subject has been fully illustrated in a paper by Mr. Russell. (*Edin. Medico-Chirurg. Trans.*) But in all cases of extensive exfoliation it is desirable that the patient should wear some artificial protection over the skull.

Suppuration of the Dura Mater.—Serious inflammation of the brain and its membranes arises often during the progress of exfoliation. This depends on the extent of injury the parts implicated have sustained at the time of the accident; or it is traceable in trifling cases of injury to a disordered state of constitution resulting from irregularities in diet, &c. In hospital practice such cases are by no means rare.

The dura mater, when both tables of the skull are dead, is one of the most important agents in the detachment of the dead bone, and it partakes of the general salutary actions which are essential to this object; but, under the circumstances just mentioned, it often becomes the seat of disease, and

symptoms set in of a character which no experienced surgeon can mistake, and which are the harbingers of fatal inflammation of the membranes of the brain.

These attacks are often so insidious in their approach that they are scarcely recognised; but careful attention to the progress of a case of this nature will not fail to detect some indisposition in the patient,—as a slight shivering, followed by a febrile attack, or some other symptom of general irritation,—enough to justify a suspicion that the membranes of the brain are the seat of incipient inflammation. It is, however, remarkable, that most extensive disease of the brain may exist, and that an abscess may occupy an entire hemisphere, without causing in its progress symptoms sufficient to justify a suspicion of its existence.

The writer has lately had under his care a case of fatal cerebral abscess occurring during exfoliation of a portion of dead bone, in which the only unfavourable symptom was an occasional attack of somnolency, which disappeared for a time, and left no trace behind. But the recurrence of these attacks, at irregular intervals, led to some suspicion that mischief was lurking within the cranium. This case will be further considered after the symptoms and pathology of suppuration of the membranes of the brain have been described, as it illustrates a point of much practical importance.

The following is the ordinary history of meningeal inflammation. A patient, in whom a portion of dead bone is exfoliating, after exposure to a blast of cold air, or from some irregularity in diet, whilst apparently progressing favourably, is suddenly seized with a severe rigor, succeeded by fever accompanied with extreme restlessness and general indisposition. Vomiting of bilious matter frequently also occurs at the beginning of the attack, and the skin, which is hot and dry, assumes a dark yellow hue. The eyes are intolerant of light, the pupils contracted, and the conjunctiva of the affected side is infiltrated with serum. The rigors and bilious vomiting frequently reappear without any regularity. There is great pain in the head, with a low muttering delirium. This is accompanied by hemiplegia and dilated pupil, and is succeeded by coma and death. If the wound is examined at any period after the commencement of the attack, the discharge, which was before healthy, will be found to have suddenly altered its character, and to have diminished in quantity; and, instead of presenting a healthy purulent aspect, it has assumed the appearance of what is commonly termed sanies; and the granulations, before florid and luxuriant, now become at first glassy, and then gradually disappear, and the bone puts on a pale yellow, or a blackish aspect. If the dead bone is raised by operation, the membrane beneath is found either in a sloughy condition, or coated with an unhealthy pus, which is sometimes contained in a circumscribed cavity, limited in extent to the size of the dead bone, but more frequently diffused over the surface of the dura mater; and the arachnoid cavity is also the seat of an unhealthy purulent secretion, either limited by a barrier of lymph, or extending over a large portion of its surface.]

Pott has given an admirable account of this formidable affection in injuries of the head. He observes,

"The symptoms attending an inflamed or sloughy state of the membranes, in consequence of external violence, are all of the febrile kind, and never, at first, imply any unnatural pressure: such are, pain in the head, restlessness, want of sleep, frequent and hard pulse, hot and dry skin, flushed countenance, inflamed eyes, nausea, vomiting, rigor, and, toward the end, convulsion and delirium. And none of these appear at first, that is, immediately after the accident; seldom until some days are passed."

This last observation, made by Pott, is one that is well worthy of the practitioner's constant recollection, lest he wrongly fancy his patient secure too soon, and neglect the early use of the only means by which a recovery can be effected. Thus, as Sir Astley Cooper notices, the time when inflammation of the brain (and it may be added of its membranes) follows the violence, is generally about a week; rarely sooner. Frequently, it does not come on till a fortnight or three weeks after the injury; and even more time must elapse before the patient is quite safe, or ought to deviate from a strict and temperate regimen. In confirmation of this remark, a case is mentioned, where the neglect to keep the bowels regular brought on a fatal attack of inflammation of the brain, as late as four months after the receipt of a blow on the head. (*Lectures, &c.* p. 339.) In University College Hospital, I have had several cases in which the bad symptoms began at very late periods after the accident.

One set or class of symptoms is produced by an extravasated fluid, making pressure on the brain and origin of the nerves, so as to impair or abolish voluntary motion and the senses; the other is caused by the inflamed or putrid state of the membranes covering the brain, and seldom affects the organs of sense until the latter end of the disease, that is, until a considerable quantity of matter is formed, which matter must press like any other fluid.

"If there be neither fissure nor fracture of the skull, nor extravasation, nor commotion underneath it, and the scalp be neither considerably bruised nor wounded, the mischief is seldom discovered or attended to for some few days. The first attack is generally by pain in the part which received the blow. This pain, though beginning in that point, is soon extended all over the head, and is attended with a languor, or dejection of strength and spirits, which are soon followed by a nausea, and inclination to vomit, a vertigo or giddiness, a quick and hard pulse, and an incapacity of sleeping, at least quietly. A day or two after this attack, if no means preventive of inflammation are used, the part stricken generally swells, and becomes puffy and tender, but not painful; neither does the tumor arise to any considerable height, nor spread to any great extent: if this tumid part of the scalp be now divided, the pericranium will be found of a darkish hue, and either quite detached, or very easily separable from the skull, between which and it will be found a small quantity of dark-coloured ichor.

"If the disorder has made such progress that the pericranium is quite separated and detached from the skull, the latter will even now be found to be somewhat altered in colour from a sound healthy bone.

"From this time the symptoms generally advance more hastily and more apparently; the

fever increases, the skin becomes hotter, the pulse quicker and harder, the sleep more disturbed, the anxiety and restlessness more fatiguing; and to these are generally added irregular rigors, which, are not followed by any critical sweat, and which instead of relieving the patient, add considerably to his sufferings. If the scalp has not been divided or removed until the symptoms are thus far advanced, the alteration of the colour of the bone will be found to be more remarkable; it will be found to be whiter and more dry than a healthy one; or, as Fallopius has very justly observed, it will be found to be more like a dead bone: the sanies, or fluid, between it and the pericranium will also, in this state, be found to be more in quantity, and the said membrane will have a more livid diseased aspect.

"In this state of matters, if the dura mater be denuded, it will be found to be detached from the inside of the cranium, to have lost its bright silver hue, and to be, as it were, smeared over with a kind of mucus, or with matter, but not with blood. Every hour after this period all the symptoms are exasperated, and advance with hasty strides; the headache and thirst become more intense, the strength decreases, the rigors are more frequent, and at last convulsive motions, attended in some with delirium, in others with paralysis, or comatose stupidity, finish the tragedy.

"If the scalp has not been divided till this point of time, and it be done now, a very offensive discoloured kind of fluid will be found lying on the bare cranium, whose appearance will be still more unlike to the healthy natural one; if the bone be now perforated, matter will be found between it and the dura mater, generally in considerable quantity, but different in different cases and circumstances. Sometimes it will be in great abundance, and diffused over a very large part of the membrane; and sometimes the quantity will be less, and consequently the space which it occupies smaller. Sometimes it lies only on the exterior surface of the dura mater, and sometimes it is between it and the pia mater, or also even on the surface of the brain, or within the substance of it, &c.

"As the inflammation and separation of the dura mater is not an *immediate* consequence of the violence, so neither are the symptoms immediate, seldom until some days have passed; the fever at first is slight, but increases gradually; as the membrane becomes more and more diseased, all the febrile symptoms are heightened; the formation of matter occasions rigors, frequent and irregular, until such a quantity is collected as brings on delirium, spasm, and death."

"When the scalp has been wounded," Mr. Pott observes, "the wound will for some little time have the same appearance as a mere simple wound of this part, unattended with other mischief, would have; it will, like that, at first discharge a thin sanies, or gleet, and then begin to suppurate; it will digest, begin to incarn, and look perfectly well; but, after a few days, all these favourable appearances will vanish; the sore will lose its florid complexion and granulated surface; will become pale, glassy, and flabby; instead of good matter, it will discharge only a thin discoloured sanies; the lint with which it is dressed, instead of coming off easily (as in a kindly suppurating sore), will stick to all parts of it; and the pericranium, instead of

adhering firmly to the bone, will separate from it, all round, to some distance from the edges.

"This alteration in the face and circumstances of the sore is produced merely by the diseased state of the parts underneath the skull; which is a circumstance of great importance, in support of the doctrine advanced, and is demonstrably proved by observing that this diseased aspect of the sore, and this spontaneous separation of the pericranium, are always confined to that part which covers the altered or injured portion of the dura mater, and do not at all affect the rest of the scalp: nay, if it has by accident been wounded in any other part, or a portion has been removed from any part where no injury has been done to the dura mater, no such separation will happen.

"The first appearance of alteration in the wound immediately succeeds the febrile attack; and as the febrile symptoms increase, the wound becomes worse and worse; that is, degenerates more and more from a healthy, kindly aspect." (*Pott.*)

The same intelligent surgeon further observes "that it is no very uncommon thing for a smart blow on the head to produce some immediate bad symptoms, which after a short space of time disappear, and leave the patient perfectly well. A slight pain in the head, a little acceleration of pulse, a vertigo and sickness, sometimes immediately follow such accident, but do not continue many hours, especially if any evacuation has been used. These are not improbably owing to a light commotion of the brain, which, having suffered no material injury thereby, soon cease. But if, after an interval of some time, the same symptoms are renewed; if the patient, having been well, becomes again feverish and restless, and that without any new cause; if he complains of being languid and uneasy, sleeps disturbedly, loses his appetite, has a hot skin, a hard quick pulse, and a flushed, heated countenance; and neither irregularity of diet nor accidental cold have been productive of these; mischief is most certainly impending, and that most probably under the skull.

"If the symptoms of pressure, such as stupidity, loss of sense, voluntary motion, &c., appear some few days after the head has suffered injury from external mischief, they do most probably imply an effusion of a fluid somewhere; this effusion may be in the substance of the brain, in its ventricles, between its membranes, or on the surface of the dura mater; and which of these is the real situation of such extravasation is a matter of great uncertainty, none of them being attended with any peculiar mark or sign that can be depended upon, as pointing it out precisely; but the inflammation of the dura mater, and the formation of matter between it and the skull, in consequence of contusion, is generally indicated and preceded by one which Mr. Pott has hardly ever known to fail; *a puffy, circumscribed, indolent tumor of the scalp, and a spontaneous separation of the pericranium from the skull under such tumor.*"

Sometimes the scalp is so wounded at the time of the accident, or so torn away, as to leave the bone perfectly bare; and yet no suppuration on the dura mater may ensue. Hence, if the pericranium be only turned back, along with the detached portion of scalp, there may be probability of its re-union; and it should be immediately made clean and replaced, for the purpose of such experiment; which, if it succeeds, will save time, and prevent considerable

deformity. Should the attempt fail, it can only be in consequence of the detached part sloughing. Hence, removing it with a knife, though allowed by Pott, is now never practised. Frequently, when the scalp does not adhere at once, it becomes attached to the cranium afterwards by a granulating process. When the detached piece sloughs, the worst that can happen is an exfoliation from the bare skull.

Sometimes the force, which detaches or removes the scalp, also occasions the mischief in question; but the integuments being wounded or removed, we cannot have the criterion of the tumor of the scalp for the direction of our judgment. Our whole attention must be directed to the wound and to the general symptoms. The edges of the former will digest as well, and look as kindly for a few days, as if no mischief was done underneath. But after some little space of time, when the patient begins to be restless, and hot, and to complain of pain in the head, these edges will lose their vermilion hue, and become pale and flabby. Instead of matter, they will discharge a thingleet, and the pericranium will loosen from the skull to some distance from the said edges. Immediately after this, all the general symptoms are increased and exasperated; and as the inflammation of the membrane is heightened or extended, they become daily worse and worse, until a quantity of matter is formed and collected, and brings on that fatal period, which, though uncertain as to date, very seldom fails to arrive.

The method of attempting the relief of this kind of injury consists in two points: viz. *to endeavour to prevent the inflammation of the dura mater; or, that being neglected, or found impracticable, to give discharge to the fluid collected within the cranium, in consequence of such inflammation.*

Acceleration or hardness of pulse, restlessness, anxiety, and any degree of fever, after a smart blow on the head, are always to be suspected and attended to. Immediate, plentiful, and repeated evacuations by bleeding have, in many instances, removed these, in persons to whom, Mr. Pott firmly believes, terrible mischief would have happened, had not such precaution been used. In this, as well as some other parts of practice, we neither have, nor can have, any other method of judging, than by comparing together cases apparently similar. Mr. Pott had more than once or twice seen that increased velocity and hardness of pulse, and that oppressive languor which most frequently precede mischief under the bone, removed by free and repeated bloodletting; and had often, much too often, seen cases end fatally, whose beginnings were fully as slight, but in which such evacuation had been either neglected, or not complied with. This judicious writer "would by no means be thought to infer from hence, that early bleeding will always prove a certain preservative; and that they only die to whom it has not been applied: this, like all other human means, is fallible; and, perhaps, there are more cases out of its reach than within it: but where preventive means can take place, this is certainly the best, and the most frequently successful.

"The second intention, viz. *the discharge of matter collected under the cranium*, can be answered only by the perforation of it.

"When, from the symptoms and appearances already described, there is just reason for supposing matter to be formed under the skull, the operation

of perforation cannot be performed too soon; it seldom happens that it is done soon enough."

In short, whenever the dura mater, after the head has received external violence, separates, or is detached spontaneously, from the bone underneath it, and such separation is attended with the collection of a small quantity of thin brown ichor, an alteration of colour in the separated pericranium, unnatural dryness of the bone, chilliness, horripilation, languor, and some degree of fever, Mr. Pott considers the operation indispensably necessary to save the patient's life.

"When the skull has been once perforated, and the dura mater thereby laid bare, the state of the matter must principally determine the surgeon's future conduct. In some cases, one opening will prove sufficient for all necessary purposes; in others, several may be necessary."

Notwithstanding the operation of perforation be absolutely and unavoidably necessary, as Mr. Pott remarks, "the repetition of bloodletting, or cooling laxative medicines, the use of antiphlogistic remedies, and a most strict observance of a low diet and regimen, are as indispensably requisite after such operation as before: the perforation sets the membrane free from pressure, and gives vent to collected matter, but nothing more; the inflamed state of the parts under the skull, and all the necessary consequences of such inflammation, call for all our attention, full as much afterwards as before; and although the patient must have perished without the use of the trephine, yet the merely having used it will not preserve him without every other caution and care." (*Pott.*)

In relation to this subject, a remark, made by Sir Astley Cooper, merits notice: when pus lies between the dura mater and skull, the application of the trephine, he acknowledges, is a successful practice; but, according to his experience, this situation of the purulent matter is comparatively rare, as it generally collects between the pia mater and surface of the brain, *for which case an operation will be useless.* (*Lectures, &c.* vol. i. p. 325.) It is stated by Sir Benjamin Brodie, that in hospital practice, suppuration between the dura mater and the bone, in consequence of fracture, is also less common at the present period, than when Pott wrote; a change which he refers to the stricter antiphlogistic plan adopted by modern surgeons, whether the early symptoms be or be not of a dangerous description. (*See Med. Chir. Trans.* vol. xiv. p. 411.)

My own observations agree with those of Sir Astley Cooper, respecting the greater frequency of purulent matter under, than upon the dura mater. Some months ago, I trephined a patient who had paralysis and other symptoms of pressure, preceded by those of inflammation within the skull. I was partly induced to do so for the purpose of removing a necrosis, which, I conceived, might extend through both tables, and be a source of irritation. The matter, however, was not under the sequestrum, which consisted merely of the outer table, but was diffused both between the arachnoid coat and dura mater, and also more deeply over the pia mater. The operation was therefore useless. In two other cases which proved fatal in University College Hospital, there was, indeed, pus on the surface of the dura mater; but there were also abscesses in the substance of the brain. Two fine specimens of this are preserved in the College Museum. The

operation of trephining, therefore, in suppuration on the dura mater, will often fail, not merely on account of the circumstances here adverted to, but because the brain and its membranes are actually in a state of inflammation. The matter may be discharged, but its pressure is not the only mischief. La Peyronie relates a case in which an incision was made in the dura mater, and a basin of pus discharged, leaving a cavity that reached to the corpus callosum. The patient recovered. (*Acad. de Chir.* t. i. p. 250.) Baron Dupuytren ventured in one instance to make a puncture, an inch deep, in the brain, and was fortunate enough to reach the abscess: the case ended well. (*Pathol. Med. Ch.* t. iv. p. 308.)

I think it not improper to recommend again the practice of applying cold wet cloths to the head for the prevention and relief of inflammation of the dura mater; a plan to which, as already explained, Schmucker ascribed a good deal of the success with which he treated injuries of the head.

Both tables of the skull sometimes exfoliate in consequence of external violence. Here the dead bone must be removed, as soon as loose; and, if necessary, the scalp divided for the purpose. M. Velpeau sets down this as a case requiring the trephine, without exfoliation being awaited, and this whether symptoms of pressure exist or not; and he gives three cases in support of this doctrine. (*De l'Opér. du Trépan*, p. 23.) I have seen cases in which the patients recovered by the exfoliation of both tables; but some of them encountered so much danger, that I suspect their chance of recovery would have been increased by acting on the principle inculcated by M. Velpeau. Yet, where the symptoms are not urgent, I should recommend awaiting exfoliation. M. Velpeau is, perhaps, rather too zealous an advocate for this practice. (*De l'Opér. du Trépan*, p. 79.)

[The puffy tumor of the scalp, mentioned by Pott as indicative of suppuration on the dura mater, although occasionally found, is generally absent. When the scalp is entire, and the bone beneath is carious or dead, there is necessarily suppuration under the scalp, and the tumor is then developed; this, however, happens wholly irrespective of the formation of pus on the dura mater. But when matter forms under the dead bone during its exfoliation, it is generally preceded by sloughing of the scalp, and the bone is consequently bared of its external covering. After injury to the skull bones, however, if symptoms of meningeal irritation occur, and if it is necessary to examine closely the condition of parts with a view to an operation, an incision should be made in any part of the cranium where there is swelling or puffiness. Hewett (*loc. cit.*) has carefully collected information from various sources on this subject, and he has come to the conclusion that the puffy tumor as pathognomonic of suppuration on the dura mater rarely exists. The writer's experience corroborates this opinion.]

Suppuration is not commonly confined to the dura mater, but it is so occasionally, and the disease is sometimes limited to the space between the dead bone and this membrane: the symptoms are then milder in their character, and rather indicate pressure on the brain than great cerebral irritation. Hemiplegia, preceded by a slight attack of fever, is frequently the only symptom present. Such cases are remediable at once by the escape of

matter when the bone is elevated. But nature often accomplishes the cure in a very simple manner: thus, small openings are formed through the bone by the granulations underneath, or at the margin of the necrosed bone, and the matter gradually oozes through, or is forced up by the heaving motion of the brain. The surgeon should now, from time to time, insinuate the flat end of a probe, and endeavour to elevate the bone, the parts being kept continually moistened with wet lint lightly laid over: soon the bone will become gradually loosened, and there will be no difficulty in raising it.

The dead bone, however, is sometimes firmly fixed in position, as if held *in situ* by atmospheric pressure, so that considerable force is required to detach it; the force should be so directed as not to risk injury to the parts beneath: a small screw attached to the end of an ordinary probe, may be carefully introduced into the dead bone, and it may be thus readily elevated, a contrivance adopted by Liston in a case of this description. If the bone cannot be raised, it must be at once perforated by the trephine, in order to relieve the brain from the pressure of matter beneath it.

Suppuration is seldom limited to the upper surface of the dura mater; it generally extends far deeper than this, and the arachnoid cavity, the meshes of the pia mater, and the cerebral hemisphere in many cases are the seat of suppuration. The symptoms mentioned by Pott, whose remarks have been quoted *in extenso*, are really not those of suppuration of the dura mater; they indicate, as it is shown from the writings of other surgeons which have been alluded to, a disease of a far more formidable character, and which the trephine is by no means calculated to rectify.

Arachnitis is indeed the prominent feature in these cases, and it is not difficult to assign a proper cause for this: in fact, there are two causes in operation at the same time in many of these cases: first, inflammation from the irritation of the dead bone, and this is common enough; and, secondly, pyæmia, which may arise during the suppurative process, and thus give rise to fatal arachnitis, terminating in suppuration in the cavity of the membrane. In suppuration resulting from the latter cause, no advantage can be expected from the trephine, and the danger is often materially enhanced by the coexistence of purulent deposits in the lungs and liver, or inflammation of the pleuræ or peritoneum.

In corroboration of the opinion as to the inutility of trephining, the cases adduced by Mr. Hewett may be referred to. These cases tend to prove that, notwithstanding they were accompanied by general pyæmia, the damaged bone and its consequent irritative effects were the primary cause of the subsequent fatal mischief. In all Hewett's cases, five in number, pus or diseased dura mater, was discovered under the denuded bone. In three, pus extended along the course of the corresponding middle meningeal artery; in all pus or sero-purulent fluid was found in the arachnoid cavity on the corresponding side; in two, pus was found in the superior longitudinal sinus; in three, the lungs were infected with pus.

Certainly the most serious cases are those in which symptoms of pressure, as hemiplegia and coma, are combined with signs of meningeal and cerebral inflammation, and which frequently coexist with abscess in the brain. In these cases, and

they are such as frequently come under observation in our large metropolitan hospitals, the operation of trephining is generally had recourse to to relieve the brain from pressure; but the pressure is really not the worst feature in the disease. Although the operation is seldom attended with any beneficial result, it would be unwise to discard it, for no harm can possibly arise from perforating a bone already dead. Hewett mentions eight cases collected from the experience of the surgeons of St. George's Hospital, illustrating this practical point; in all, symptoms of pressure coexisted with those of cerebral inflammation and effusion into the arachnoid; in all, the operation was performed with no relief to the symptoms; but no harm in any instance resulted from the use of the trephine. This collection of cases is valuable also, as demonstrating a most serious complication of pathological conditions revealed after death, as suppuration in the diploe, matter and lymph on the dura mater, sero-purulent fluid in the arachnoid cavity and sub-arachnoid cellular tissue; pus in the sinuses of the dura mater, secondary deposits in the lungs, liver, &c.; thus showing a deep-rooted pyæmia, over which no treatment whatever appeared to have had the slightest influence. Yet in all these cases, wherever pressure existed, the seat of pressure was indicated by the hemiplegia on the side opposite to that where the effusion took place. This circumstance is important, as leading to the site where the trephine should be applied, and in this very important respect it forms a strong contrast to cases mentioned by Pott. So also the seat of the purulent effusion on the dura mater corresponded in all with the disease of the bone.

When the abscess in the arachnoid cavity is circumscribed, the pus is usually similar to that in other abscesses, and it is contained in a cavity bounded by a wall of lymph. Under these circumstances the case may ultimately do well. Hewett quotes a case from Mr. Guthrie of this description: in this, "after the removal of bone by the trephine, the dura mater rose up in the opening without any pulsatory motion." Mr. Guthrie punctured this, "and a considerable quantity of matter escaped. This continued for some time; granulations formed, and the patient was eventually cured."

Mr. Hewett also gives an interesting case from Roux, in which a fistulous opening remained in the back part of the parietal bone in a young man who some years before, had a blow on the back of the head. This discharged a considerable quantity of matter at various times. The patient became subject to attacks of drowsiness when the discharge ceased. The bones were exposed, and the trephine was applied; three ounces of matter escaped. "An opening, the size of the top of the finger, was found in the dura mater, leading into a cavity, the deep surface of which was red, and presented a cup-like depression. No untoward symptom followed the operation, and the patient was cured at the end of two months." (*Hewett, loc. cit.*) It is not improbable that the abscess was situated in the brain itself; at any rate it points out the necessity and occasional advantage of applying the trephine.

When a piece of bone has been removed by the trephine, and the matter on the surface of the dura mater has been discharged, if the latter membrane is pushed up so as completely to fill the opening; and especially if this occurs where no

matter has been discharged on the surface of the dura mater, it is the duty of the surgeon to puncture this membrane, provided the pressure is unrelieved, and the membrane is altered in character; as a cerebral abscess may exist beneath, and the escape of matter may save the patient's life. If, however, the opening is made into the arachnoid cavity, we cannot anticipate much benefit: if well-formed pus escape, the prognosis is more favourable than where the fluid is of a sero-purulent character, for the latter is characteristic of diffused arachnoid inflammation, the former of a circumscribed collection of matter.

But, perhaps, the membrane has been punctured, and no matter is discovered, either circumscribed or diffused; and the opening is found then filled by the rising up of the brain itself. What is to be done under these circumstances? In other words, are we to puncture the brain itself, and to explore it with the grooved needle? This question is not so readily answered, for the diagnosis of cerebral abscess is by no means easy; indeed, there is so much difficulty and uncertainty on the subject that prudence dictates the greatest caution. We would suggest, in the absence of positive signs of pressure, that no puncture should be made.

We ourselves have seen, and the same has occurred to other surgeons, the brain pushed up into the aperture of the skull after the dura mater has been opened; and the surgeon has been tempted to puncture the brain under the impression that an abscess had formed in it, and no matter has escaped. We have had a case recently under our own care, in which it was thought requisite to trephine; and immediately, on dividing the dura mater, the convolutions of the brain were pushed upwards through the opening. The brain was not punctured, but it was thought that matter existed in some part of the organ; and this really was the fact, for although there was an exceedingly small collection of matter found in the brain near the opening, this might be attributed to the inflammation which occurred after the operation; but there was an abscess in the anterior lobe of the opposite hemisphere, and another in the ventricle of the same side. The result of the examination of this case is given, because the matter was very different to that which is usually found in common abscesses, and the examination may possibly illustrate the ordinary condition of cerebral abscess: it was of a greenish-yellow colour, such as is generally found in cerebral abscess; the internal wall of the abscess was smooth, yellow, dense, and friable, but not membranous. Immediately external to this, the cerebral substance was of a deep yellowish-red colour, and dotted with red specks, and increased in density. About half an inch external to the abscess, the brain exhibited its normal character. The matter contained in the cavity consisted of a *fluid holding in suspension hyaline globules, granule cells, blood discs and free granules*. The wall of the abscess appeared to be made up of disintegrated brain substance mixed with free granules, granule masses, and granule cells. Immediately external to the wall of the abscess, the cerebral substance was found infiltrated with a homogeneous substance. The nerve tubules in this part were remarkably large and varicose, and granule cells were abundantly present between them.

The simultaneous occurrence of abscess in the substance of the brain, with suppuration on the dura mater during exfoliation, especially if the abscess is formed at a distant part, is not unfrequently the cause of much obscurity. The case just related is an instance of this; for, although hemiplegia, which we regard as the most important symptom of pressure, was by no means well developed, it existed, nevertheless, to a slight extent on the right side, and on this side the bone was necrosed. It was therefore evident, on careful consideration, that, according to the known law of the cross-action of the brain, it could not depend on the effusion of matter beneath the dead bone, for in that case the hemiplegia, slight as it was, would have been on the left side; the inference, therefore, was, that the principal mischief was to be sought for on the left side, and on this side an abscess was discovered in the cerebral hemisphere, and far out of the reach of any surgical relief by operation. The trephine was applied in this instance with scarcely any expectation of benefit, and we were not much disappointed at the result. A recent and better marked instance of this source of embarrassment has occurred under our own observation, which exemplifies the same circumstance more clearly, and may be regarded as a proof of the unerring nature of the phenomenon that paralysis on one side of the body is always dependent on pressure on the opposite side of the brain. A man was admitted into the London Hospital, with a granulating wound of the scalp in the forehead, slightly out of the mesial line on the right side. The accident had been caused by a blow from a stone, which rendered him senseless for half an hour; in falling he struck the back of his head against the kerbstone. He went afterwards to his work as usual, and was admitted in about three weeks after the accident. When first seen he looked ill, but made no decided complaint. A piece of dead frontal bone was found at the bottom of the wound, which was removed with great facility; there was another dead portion, which was left, as it was not separated. In about three days after this he had slight paralysis of the right side of his face, and was very unwell, and on the sixth day after the whole right side of his body became paralysed. Mr. Ward judiciously removed a piece of bone with the trephine, and found about a drachm of pus on the dura mater. As matter seemed to well up in the direction of the left side, another portion of bone was removed, and the angles between the openings in the bone were sawn off. He appeared somewhat relieved at first, but he gradually became worse, and, in consequence of the persistence of the paralysis on the right side, and as the wound was close to the mesial line over the longitudinal sinus, the trephine was applied on the left side, but no matter was discovered on the dura mater. He sank gradually with symptoms of pressure about a fortnight after the first operation. There was found, on examination after death, a large abscess in the *left* hemisphere of the brain, which had gradually made its way upwards to the surface, and some of the matter had escaped through an ulcerated opening of the dura mater.

Both these cases are valuable illustrations of the fact of the hemiplegia being on the side corresponding to that on which the original injury was inflicted,

although it was dependent on an abscess in the opposite cerebral hemisphere; they also prove that, when a piece of bone is exfoliating on one side of the cranium, the opposite cerebral hemisphere may be the seat of fatal inflammation, and, further, that such fatal inflammation resulting in abscess may occur, as it did in the first case, without any very appreciable symptoms.

In the treatment of meningeal inflammation occurring during exfoliation of bone, we are not disposed to advise the free employment of bleeding either by the arm or by leeches, as recommended by Pott in such cases. The disease so commonly attacks patients of a depraved state of constitution, in whom no violent depletory measures can be borne, and in whom the loss of many ounces of blood from the arm would irretrievably depress the vital powers beyond all hope of recovery. Nevertheless, a mild anti-inflammatory treatment, as is implied in the careful administration of mercury and saline medicines, with cold applications to the head, is infinitely preferable to the indiscriminate use of stimulants, which it is too much the custom to administer in the present day. It is, however, very necessary to employ the greatest circumspection during the entire treatment of all cases of exfoliation of bone necrosed from injury, for the prognosis, after meningitis has set in, is in most cases exceedingly unfavourable.]

FRACTURES.

[Under the head of fractures will be included all solutions of continuity of the bones immediately resulting from external violence: thus in this classification are enumerated incised wounds of the skull, penetrating or punctured wounds, diastasis or separation of suture, simple fracture or fissure, indented fracture, depressed fracture, and fractures of the base. Many fractures of the skull, being complicated with wounds of the scalp leading to the fracture, are necessarily compound, according to the recognised surgical nomenclature; whilst fractures of the base for the most part belong to the class of simple fractures. Fractures have been also arranged under the heads of direct fractures and fractures by *contre-coup*. But, whatever the nature of the fracture, its practical importance has a distinct relation to the state of the brain resulting directly or indirectly from the fracture. Hence it is customary in allusion to this subject to speak of a fracture of the skull with or without symptoms of concussion or compression; and in forming a prognosis of such cases, or in laying down a plan of treatment, a knowledge of the condition of the brain, as indicated by certain symptoms, is of essential importance.

Incised wounds of the skull.—Injuries produced by cutting instruments, such as sabre-cuts, will be first considered, as they approach in character nearest to simple incised wounds in other parts. It must be at once apparent that no clean incision can be made through the cranium without the application of immense force. As the occurrence of such accidents is comparatively rare in civil life, we may refer principally for their description to writers on military surgery. Incised wounds of the skull may be arranged under the following heads:—First, the simple section of the outer table, in which a mere superficial mark is left;

secondly, the division of both tables by a perpendicular section; thirdly, an oblique or horizontal cut, where both tables are divided, but not completely detached; and fourthly, the entire ablation of a piece comprising both tables, in which the bone adheres to the soft parts, or is completely removed with them. In the first two it should be borne in mind that the internal table of the skull may from the peculiarity of its structure be injured to a much greater extent than the external, and it is absolutely impossible from the mere inspection of the wound to ascertain the amount of injury the inner table has suffered; for, notwithstanding the apparent slowness of the incision, and even when there is no ocular evidence of the instrument having penetrated the cranial cavity, a piece of the vitreous table may be broken off, and may eventually become a cause of the most serious irritation to the membranes of the brain. From the vaulted form of that part of the skull in which these accidents most frequently occur, it is almost impossible that any lengthened vertical section of both tables can be made without a wound of the dura mater, a complication of the greatest interest. The simple incision of the skull is readily ascertained by inspection, and if there are no signs of compression, or any other injury to the brain, the edges of the divided scalp should be accurately brought together; cold applications, as ice, should be employed, and a strictly antiphlogistic treatment be enjoined. If, however, decided symptoms of pressure on the brain exist, the surgeon is justified in removing a piece of bone with the trephine, as it is possible that the inner table of the skull may have been fractured and detached, or one of the large arteries of the dura mater may have been lacerated. The position of the injury, and the gradual supervention of the symptoms, afford a clue to the nature of the case, as such an accident in the temporal region would suggest the possibility of a division of the spinous artery. When the instrument has penetrated both tables of the skull, the nature of the case is recognised at once by the visible pulsation of the brain through the fissure; and, the blood gradually welling up, no pressure takes place from accumulation on the surface of the dura mater. If the dura mater is intact, and the blood which is effused escapes freely, the case must be treated as in more simple forms of injury; but if the dura mater is divided the danger is materially enhanced, as there is great risk of arachnitis with all its consequences. Nevertheless, in the absence of all signs of pressure on the brain, the trephine is unnecessary, as the operation may increase the danger. Cold lotions must be sedulously applied to the head; bleeding locally and generally, with free drastic purging, comprise the category of remedies, to allay any cerebral mischief. The scalp should be carefully but lightly adjusted, and retained in position by sutures; an exit must be given to the blood, which otherwise is either pent up on the surface of the dura mater, or escapes into the arachnoid cavity, and thus gives rise to pressure on the brain. Although in wounds of the skull by sabre-cuts, or by any other means, there is some suspicion that the inner table of the skull is splintered, or a portion of it detached, if no symptoms indicating pressure or meningeal irritation, as coma, convulsions, &c. are present, it is desirable to abstain from the introduction of the probe to

ascertain the extent of mischief. But we are averse to give a positive opinion on a subject on which military surgeons only are competent to decide: experience alone can justify a proceeding which is at any rate somewhat hazardous. Mr. Guthrie advises that a blunt or flat-ended probe should be carefully passed into the wound, and, being gently pressed against one of the cut edges of the bone, its thickness may be measured, and the presence or absence of the inner table may thus be ascertained. It must be confessed that this appears to be a most unsatisfactory mode of proceeding, nor is it clear what information can be gained by it, and in the absence of symptoms, we think, notwithstanding such high authority, the case had better be let alone. If, however, symptoms of meningeal irritation exist, then it may be advisable to introduce the probe to ascertain the condition of the inner table; if this is found loose and movable, it will be necessary to remove it, lest it become a source of further irritation to the dura mater. On the subject of the re-application of the partially detached parts in sabre-cuts, Hennen (*Military Surgery*) says, "Sabre-cuts admit frequently of being at once replaced, and in many instances, with the aid of a few stitches and proper supporting bandages, they adhere without further trouble. In some inflicted by our own and the French dragoons in Spain and Belgium, sections of the scalp, cranium, and even of the brain, were frequently made, and in many instances were successfully treated by simply laying the parts together. Lamotte mentions a case where, by a stroke of a dragoon's sabre, the skull was cleft through the right parietal bone to the depth of two inches, and the left between three and four, down to the ear. This severe wound was cured in less than three months. Professor Thomson mentions a remarkable instance, in which a considerable portion of the occipital bone with the dura mater had been removed; a tendency to protrusion of the brain took place during an attack of inflammation; a slight degree of stupor with loss of memory occurred; but, the inflammatory state having been subdued, the brain sank to its former level, the stupor disappeared, and the memory returned. And in another case the cerebellum was even pulsating for a period of eight weeks, yet the injury was unaccompanied by any peculiar symptoms."

Hennen remarks that the opinion is current amongst writers on military surgery, "that sabre-cuts on the top of the head are not by any means so dangerous as those on the sides. This I have often had occasion to observe in my own practice as well as from the report of others. In some sabre-cuts which divide the skull across the sagittal suture, the longitudinal sinus has been occasionally opened and bled profusely, but without inducing fatal consequences. I have seen this sinus opened by splinters, but never saw anything approaching to dangerous hæmorrhage from it: in truth, the bleeding from wounds of the head is one principal source of the patient's safety." (*Hennen, op. cit.*)

Punctured wounds of the skull.—Punctured wounds of the skull are invariably attended with the greatest possible danger, as the brain is necessarily wounded if the instrument has penetrated to any depth. They occur from bayonet thrusts, and were frequent when the

arrow was the principal weapon used in war. There are but few situations where an instrument can penetrate the cranium without fracturing the bone; but it is nevertheless possible: for a sharp-pointed instrument can be directed into the skull through the foramen lacerum orbitale, or from the back part of the neck, between the first and second cervical vertebræ, and through the foramen magnum. The extent to which the instrument has penetrated cannot generally be ascertained; and it has sometimes happened that the external wound has become completely healed, whilst destructive mischief lurked within the cranium.

In the *Clinique Chirurgicale* of Baron Larrey the case of a grenadier is mentioned, who during the escape from Moscow received the stroke of a lance from a Russian soldier at the posterior part of the head. The instrument passed deeply into the skull in the direction of the posterior lobe of the brain. The man recovered, but with the loss of the functions of most of his organs of sense. His intellect remained unimpaired, and his limbs were but slightly affected, there being a trifling paralysis. His voice became hoarse and was gradually lost. His hearing, taste, and smell became impaired; the muscles attached to the larynx being paralysed, this organ was depressed half an inch below its natural level. From the difficulty he experienced in drawing the air through the larynx in inspiration, he was obliged by a sudden action to raise the larynx and pharynx, and to gulp the air something after the manner of a frog in the act of breathing; the diaphragm being also partially paralysed. Larrey presented him to the Philomathic Society, and the man was nearly choked whilst his jaws were held apart during his examination by that learned body. The muscular structure of the pharynx, œsophagus, and stomach, were partially paralysed, as deglutition was accomplished with difficulty, and vomiting could not be excited. The pulse was slow and feeble, indeed scarcely perceptible. But his intellect remained unimpaired, and he wrote all his answers to questions put to him.

Larrey also mentions another instance of punctured wound of the cranium through the right orbit, inducing paralysis and other signs of cerebral injury, and this patient survived beyond the third month after the injury. The course of the instrument was indicated after death by an oblique canal which traversed the right hemisphere, and, entering the left, passed over the left optic nerve, injuring the root of the right, and was arrested at the floor of the left lateral ventricle. The canal was lined by a thin coagulum of blood.

The orbital plate of the frontal bone, from its position and extreme thinness, is liable to punctured fracture. We have seen this accident as the result of the introduction of the prongs of pitchforks in agricultural labourers. In one case a man was drawn up from the hold of a ship in consequence of the hook attached to a basket of coals having given way and entered the orbit: these bodies, necessarily directed upwards, enter the skull through the orbital plate of the frontal bone, passing first through the skin of the upper eyelid, or through the conjunctiva; the brain is generally penetrated, and the consequences almost invariably fatal. In these cases a surgeon may be deceived as to the extent of the injury, for the wound is small, and in some instances

speedily heals; and as there is much ecchymosis of the orbit and eyelids, the aspect of the case is that of a simple contusion. Moreover, symptoms of severe cerebral mischief rarely make their appearance until after twenty-four hours from the time of the accident. Sometimes, however, from the very commencement cerebral symptoms, as convulsions, insensibility, and stertorous breathing, appear, and indicate severe cerebral injury; or a slight shivering or strabismus leads to the suspicion of the true nature of the case. In all cases the orbit is distended with blood, and the eye is sometimes protruded, extensive ecchymosis being visible beneath the ocular conjunctiva.

Morgagni says: "Numerous cases are registered in medical works in which the patient survived an injury of the brain occasioned by a wound through the orbit, for nine, twelve, fourteen, or even twenty-one days; but I have met with no instance in which there was a more complete exemption from inconvenience than this. In some cases alluded to, the animal functions indeed appear to have been but slightly disturbed till near the period of decease. But injuries of this nature have not invariably proved fatal, for, even where amaurosis of the corresponding eye and paralysis of the opposite side have resulted, the patient has been known to survive."

"The upper part of the orbit is so thin that wounds inflicted with a pointed instrument in that direction are not to be lightly regarded, especially if there be a supervention of sleepiness, nausea, fever, vertigo, or any sign of paralysis." (*Cooke's Translation of Morgagni.*)

In cases of recovery after supposed penetrating wounds of the orbit, it is probable that the instrument has not passed beyond the boundaries of this cavity, and that amaurosis and strabismus have resulted from simple lesion of the nerves of the orbit. This observation is inapplicable to cases where hemiplegia has existed. Hewett has collected many cases of this character, and they tend to exemplify the same facts: namely, the obscurity as to their precise nature at first; secondly, the supervention of severe symptoms within a comparatively short time from the accident; and, lastly, their almost invariable fatality.

The fatality in these cases results from the injury inflicted on the brain, and the consequent extravasation and subsequent inflammation; and it is obvious that, whatever treatment be pursued, there can be no possible room for escape of the extravasated blood, or the necessary products of the inflammation. The opening through the bone is generally too small to admit of the escape of the damaged brain, and the pent-up matter produces pressure, from which there can be no hope of relief. We entertain a very strong opinion that if the brain is wounded through the orbit, recovery is almost impossible. South, however, in his translation of Chelius' *System of Surgery*, quotes a remarkable instance of recovery from a wound of the brain through the orbit. The case is given by Dr. Selwyn, of Cheltenham: "A knife, a common cheese-knife, about four inches and a quarter long in the blade, and averaging three-quarters of an inch broad, entered the right orbit nearly horizontally, to the depth of three inches and a quarter, immediately beneath the supraciliary ridge, and penetrating, through the posterior part of the orbital plate of the frontal bone, the substance of the

brain, injuring in its course the optic nerve and the levator palpebræ muscle or the nerve supplying it. It required all the father's force to dislodge the knife from its situation. The hæmorrhage was very slight. After the removal of the knife some portion of the brain protruded; more was discharged on the eighth day after the accident. He did not sleep for a fortnight after the accident, and was delirious during the night. The treatment consisted of low diet, little or no medical treatment, and the application of strips of adhesive plaster to the wound, which was healed in six weeks. There was never any exfoliation of bone. The vision is entirely lost in the eye, the pupil dilated, and wholly insensible to the stimulus of light. All the senses are perfect except the vision of the injured eye. The memory is very defective, and he is incapable of applying to any pursuit requiring mental activity. His health is good, and he has the free use of his limbs." (*South's Chelius*, vol. i. p. 397.)
